KENDALL'S *Bacteriology* is a well known textbook in America, and the second edition<sup>4</sup> has been brought up to date. Dr. Kendall, who is professor of bacteriology in the Northwestern University School of Chicago, has made many contributions to the study of the bacteriology of the intestinal tract, and a section of the present volume contains a special chapter devoted to the gastro-intestinal flora of normal infants, adolescents, and adults; in this chapter also the significance of intestinal bacteria and the wholesome activities of the industrious inhabitants of the intestines are justly appraised. Another branch of the science in which Dr. Kendall has carried out valuable research is that which deals with the metabolism of bacteria. It is to this department more than to any other that we must look for the unravelling of the mysteries which attend the subject of the parasitism of bacteria. The physiological method will also probably come to be the only method of classification available, since morphological appearances and even cultural characteristics have failed to differentiate between closely allied strains.

The book before us is divided into five sections. The first deals with general bacteriology and is concerned with the morphology, general physiology, and chemistry of bacteria. Then follows a chapter on bacterial metabolism, in which the author contrasts the growth of organisms in media containing utilizable nitrogenous substances and carbohydrates and in media containing only utilizable nitrogenous substances; in the former case the carbohydrate is used for energy requirements in preference to the protein, which is not at first attacked by the bacterial ferments, whereas in the latter case the protein is made use of from the beginning. This phenomenon is known as the "sparing effect of carbohydrates on proteins"; but the rules the author lays down can scarcely be said to be of universal application, for there are some bacterial species which do not show any selective preference for carbohydrates, and seem, in fact, to hesitate before they finally make use of these sugars. The remainder of this section deals with immunity, questions of technique, and sterilization, antiseptics, and disinfection.

The second section, on pathogenic bacteria, passes in review the different groups of disease producing bacteria. The main facts about each organism are clearly presented, but though the author describes in detail the recent work carried out on the other side of the Atlantic on the grouping of such an organism as the pneumococcus he says little about similar researches undertaken in this country on dysentery, perhaps because they have not been so widely advertised. In general it may be said that this section of the book is not so comprehensive nor so helpful to students as the descriptions found in other standard textbooks.

Section 3 deals with the higher bacteria, moulds, yeasts, filtrable viruses, and diseases of unknown etiology. Reference has already been made to Section 4, on gastro-intestinal bacteriology, and the last section on applied bacteriology explains the bacteriology of milk, soil, water, and air. There are two minor merits of this textbook to which reference should be made, one the manner of printing and the other the illustrations. The headlines and spacings of the paragraphs make the book easily readable, and the 8 coloured plates and 99 engravings illustrate the points described with great clearness. This book is not likely to take the place of the standard textbooks used in this country by students, but it will be a useful reference book, both because the author speaks with the authority of an original investigator in many provinces, and because he has supplied liberal references to articles and monographs dealing with subjects for which he has not felt justified in sparing more space.

#### BRONCHOSCOPY AND OESOPHAGOSCOPY.

Dr. CHEVALIER JACKSON has produced a book entitled *Bronchoscopy and Esophagoscopy*,<sup>5</sup> which is based on an abstract of his larger work, *Peroral Endoscopy and Laryngeal Surgery*, published in 1915. The new book is especially welcome, since it contains everything essential that was to be found in the earlier work, but the bulk has been greatly reduced by the omission of redundant matter and of many unimportant illustrations. The present volume naturally has been brought up to date in certain details.

In the first chapter, one of the most important, entitled "Instrumentarium," the author now describes only the apparatus with distal illumination, with which his name is so closely associated. He thus gives the fruits of his own unique experience in the designing and manipulation of instruments for this work, and any attempt to seek completeness by compilation is avoided. It is a little difficult to understand how anyone can continue to use the older instruments with proximal illumination after experience with Jackson's distally illuminated tubes and specula, the objections to which are purely theoretical. Those who do so continue will find here no support. In this branch of surgery improvisation plays no part; a complete and appropriate selection of instruments and a detailed knowledge of every manoeuvre or manipulation that may be necessary to expose and disengage an impacted foreign body are essential to success. Advice as to all this is to be found in the present invaluable book. The author is equally helpful when he writes on the diseases to the examination and treatment of which endoscopy may be applied.

A particularly complete and helpful account of diseases of

<sup>3</sup> *Physical Examination of the Chest*. By James Crockett, M.D., D.P.H., M.R.C.P.E. London: H. K. Lewis and Co., Ltd. 1922. (Cr. 8vo, pp. viii + 251; 53 figures, 14 plates. 5s. net.)

<sup>4</sup> *Bacteriology: General, Pathological, and Intestinal*. By A. I. Kendall, D.M., Ph.D., D.P.H. Second edition. Philadelphia and New York: Lea and Febiger. 1921. (Med. 8vo, pp. xi + 650; 99 figures, 8 plates. 6dols.)

<sup>5</sup> *Bronchoscopy and Esophagoscopy: A Manual of Peroral Endoscopy and Laryngeal Surgery*. By Chevalier Jackson, M.D., F.A.C.S. Philadelphia and London: W. B. Saunders Company. 1922. (Med. 8vo, pp. 345; 114 figures, 4 plates. 27s. 6d. net.)

the oesophagus from the point of view of the endoscopist is given. For example, twenty-nine causes of oesophageal dysphagia are enumerated, an indication of the difficulty and complexity of this aspect of the subject.

The subject of tracheotomy is perhaps scarcely comprised in the title of the book, but it is so closely related and the chapter describing it so full of information derived from the mature wisdom and experience of the author, that he is heartily to be congratulated on including it. A careful study of it should do much to reduce the mortality following this operation. If any portions of the book can be chosen as valuable beyond the rest they would be this chapter on tracheotomy and those entitled "Bronchoscopic foreign body extraction" and "Esophagoscopy for foreign body." No laryngologist can afford to neglect a careful study of this book nor to be without it or its larger parent for reference in case of emergency. There is much, too, that will be helpful to several surgeons, who are frequently confronted with problems on the border-line between general and special surgery.

### MEDICAL APHORISMS.

PROFESSOR J. A. LINDSAY of Belfast has published the *Medical Axioms, Aphorisms, and Clinical Memoranda*<sup>6</sup> that have been familiar to several generations of his students. The title recalls and indeed suggests a resemblance to "Clinical Aphorisms from Dr. Geo's Wards" first collected by Sir Thomas Horder in the *St. Bartholomew's Hospital Reports* for 1896, to the latter's *Medical Notes* published two years ago, and to Sir James Fowler's chapter of *Obiter dicta* in his recent (1921) *Pulmonary Tuberculosis*. That there is some resemblance is unavoidable; but there is this wide difference, that whereas his predecessors' collections were practically confined to their own remarks, Professor Lindsay supplements his own aphorisms by a judicious selection from the sayings of over 140 authorities, beginning with Hippocrates and including many still active in teaching. Some of the quotations are from non-medical thinkers, such as Benjamin Jowett, Francis Bacon, and Beethoven.

The contents are arranged under the heads of general remarks, lungs and pleura, the cardio-vascular, digestive, and nervous systems, and miscellaneous (such as alcohol, renal disease, and fevers); the contents of the final category, headed philosophical, are nearly all quotations from others. It is not perhaps safe to assume that the aphorisms without someone's name attached have all been constructed by the author, for among those there is the well known "A man is as old as his arteries," which has not got Cazalis's name appended; and again, "For one mistake made for not knowing, ten mistakes are made for not looking," is certainly familiar in sense if not in this exact form. "Nature is a good physician but a bad surgeon" rings new and true; but "Tell the elderly not to forget *Anno Domini*" does not appear to be entirely a wise counsel, though there may be some ambiguity about what is to be remembered. But as there are nearly a thousand separately numbered expressions of opinion, and the field covered is very wide—with references to quinidine and insulin—it would indeed be remarkable if there was no one open to discussion; besides, many of us derive a good deal of pleasure from reading the aphorisms of others in a critical spirit. To these and other members of the medical profession Professor Lindsay's handy little volume will be a happy hunting ground and source of reference.

### SEQUELS OF ENCEPHALITIS LETHARGICA.

THE immense body of literature on epidemic encephalitis which has accumulated in the last few years has so far failed to provide the practitioner with any very clear ideas as to the sequelae or the final prognosis of this distressing disease. Hence Dr. Lévy's monograph<sup>7</sup> comes as a timely addition to our knowledge and confirms the terrible results which may follow an acute attack of encephalitis lethargica. Her account and conclusions are based on a study of 129 cases in the clinic of Professor Pierre Marie at the Salpêtrière; many of the patients have been followed for several years, and some down to their death. After distinguishing between the

symptoms which arise during the acute period of the disease, even when this is prolonged, and those which follow after a period of latency, the author points out that this latent period may vary very much—from, in fact, a few weeks up to or even more than two years. Another point of great importance is that the initial form of the disease is no criterion of the form which any sequelae may assume. Thus a case which in the acute period has shown the myoclonic syndrome may later develop the Parkinsonian syndrome, and so on.

In a classification of the sequelae the author found that no fewer than 73 showed the Parkinsonian syndrome, the so-called symptomatic paralysis agitans, a fact confirming the experience of many in this country; 43 cases showed excitomotor syndromes, including various forms of involuntary movements, choreiform, myoclonic, localized movements of the face, and what the author terms bradycinesis, by which we understand a slow involuntary movement rather resembling the movements of athetosis. Other sequelae of especial interest are obesity and disturbances of the respiratory rhythm.

The clinical descriptions of these various syndromes are full of detailed interest and are a monument of careful study, the account of the Parkinsonian syndrome being particularly good. It is perhaps to be regretted that the author has not been able to include a more detailed study of the mental disturbances which may follow the disease, for greater knowledge of such forms of psychosis is badly needed.

There are short sections on the morbid anatomy and the pathogenesis. In four cases of the Parkinsonian syndrome atrophy of the cellular elements was found in the basal ganglia and locus niger and in one case degeneration of the myelin in the centrum ovale. It is especially interesting to note that in one case the persistence of signs of active lesions was observed—for example, perivascular infiltration—in the mesencephalon. The author concludes that it is reasonable to suppose that in a certain number of cases the virus remains active. There is a useful chapter on the changes in the cerebro-spinal fluid and their diagnostic value.

There are a good bibliography and some valuable illustrations. Enough has been said to show that Dr. Lévy has given us a very valuable study. We hope that neurologists in this country will follow her example and let us have the benefit of their experience in this very important matter.

### THE COMPOSITION OF SCIENTIFIC PAPERS.

"Every man who understands the art of writing, and has tried to write well, is aware that the process of composition is commonly not the simple transference of thought into language, but the laborious attempt to work into a coherent shape ideas which have been in his mind, but which have still to be clarified and arranged."

COMING upon these words one day in an article on "The decay of syntax," our thoughts turned at once to Sir CLIFFORD ALBUTT and his book of counsel to medical writers. At that time the second edition of *Notes on the Composition of Scientific Papers* had been out of print several years, and those needing literary first aid were complaining that they had to borrow the book or go without. The third edition,<sup>8</sup> so many years overdue, has now appeared, and we welcome it almost like the return of a long expected friend. Scanning its features with the affectionate interest proper to such occasions, we find at first glance everything much as before; the familiar green cover is there, the print is the same, the size and shape of the page are unchanged. The author's accumulated honours and distinctions of eighteen years have, of course, left their traces on the title-page. A few pages—some twenty or so—have been added in all; there is now a short index to help the diligent reader, and a still shorter appendix forming a kind of kennel for dog-latin words.

On closer study, and comparison with the edition of 1905, we perceive many marks of a pruning knife wielded with a firm hand. This is by no means a reprint, but a new edition very thoroughly revised in every part. Sir Clifford Allbutt has edited himself unflinchingly; it is the same book, yet not quite the same; here a little has been put in, there a little taken away. Let it be said at once that every word of the added matter is good and to the point, but rigorous revision has cast out some familiar passages which many will think

<sup>6</sup> *Medical Axioms, Aphorisms, and Clinical Memoranda*. By James Alexander Lindsay, M.A., M.D., F.R.C.P., Professor of Medicine in the Queen's University of Belfast. London: H. K. Lewis and Co., Ltd. 1923. (Cr. 8vo, pp. viii + 192. 6s. net.)

<sup>7</sup> *Contribution à l'Étude des Manifestations Tardives de l'Encéphalite Épidémique*. By Dr. Gabrielle Lévy. Paris: Vigot Frères. 1922. (Roy. 8vo, pp. 314; 53 figures. Fr. 18.)

<sup>8</sup> *Notes on the Composition of Scientific Papers*. By the Right Hon. Sir T. Clifford Allbutt, P.C., K.C.B., M.A., M.D. Third edition. London: Macmillan and Co., Ltd. 1923. (Cr. 8vo, pp. 192 + xiv. 6s. net.)

too good to lose. Remembering its purpose, few would have grumbled had the book grown with the passage of time.

The preface seems largely new. In Chapter I we find a fresh paragraph on names and terms, a greater emphasis on the need for lucidity in composition, and a caution against the abuse of hospital, laboratory, and military slang. In Chapter II the section on participles and gerunds has been expanded; and the "woolly style," with its "litter of idle words," is now attacked with a larger battery. Time, we note with satisfaction, has deepened the author's dislike for such borrowed words as questionnaire, résumé, and rôle; and we may feel sure that he would subscribe to Mr. John Bailey's opinion that "the only safe rule when writing English is to write it, never using a foreign word where an English one exists." The split infinitive and other uncouth suspensions tease him as much as ever. His indictment of the split infinitive is as good as anything in the book; yet we cannot help thinking that, while the general rule is sound, it may be pedantic always to invert the phrase in order deliberately to avoid the split. But we must not be tempted into detailed discussion; nor must we, by debating verbal niceties, suggest to those who are not familiar with this little classic that Sir Clifford Allbutt puts form above substance, style above stuff. A sentence from the preface may therefore be quoted:

"It is far from my intention in these simple instructions to advocate a manner of writing in which pith and character are lost in polish or affected elegance; indeed, my purpose is literary only so far as to insist on the qualities of clearness, precision, and definition."

Enough has been said, we hope, to commend this new edition to our readers, young and old. Changes have been made, but the spirit of the book burns as brightly as ever. If we should seem to write of it with too much enthusiasm we reply that the medical editor by the nature of his work feels more often than others the need of such advice. Some may think the standard set too high for ordinary mortals; nevertheless the reading and re-reading of this small treatise will help us so to order our thoughts and fashion our language, that when we have something to say we may write it in the fewest and the best words and no one can doubt our meaning.

# NOTES ON BOOKS.

*The Yearbook of the Universities of the Empire*<sup>9</sup> has become a reference volume indispensable to all interested in university and professional education. It summarizes the calendars of the sixty-six universities and colleges of the British Empire, and into a volume of manageable size, without sacrificing intelligibility to brevity, the editor compresses details of their degrees, courses of study, staffs of professors and lecturers, and other essentials. In the present edition the new University of Delhi, the West Indian Agricultural College, University College, Colombo, and the King Edward VII College of Medicine, Singapore, appear for the first time. One section of the appendix deals, in a rather briefer way, with foreign universities all over the world; another section gives a summary of British medical and dental qualifications and the requirements necessary for registration; and another is devoted to a short account of the scholarships and grants for research available in this country and abroad. The index of names at the end of the volume we have in previous years found useful and accurate for ascertaining quickly the university or college at which any particular British scientist holds an appointment and its precise title.

*The Minutes of the General Medical Council and of its Various Committees for the Year 1922* (Vol. LIX) has been issued.<sup>10</sup> The volume contains twenty appendices, of which the most important are those giving the Education Committee's report on the revision of the curriculum in medicine, and the Public Health Committee's report on the revision of the regulations and rules for the diplomas and degrees in sanitary science, public health, and State medicine. In 1903 the Council issued an index to its minutes, and it was then determined not to allow so long an interval to elapse in future. A new edition was issued in 1908, and the index has since been kept up to date. The issue for this year<sup>11</sup> covers the twenty years 1903-1922.

Some years ago Dr. E. LE BEC wrote a book, *Preuves Médicales du Miracle*, which is well known to the majority of those who have taken an interest in Lourdes. It has now been translated into English by Dom H. E. IZARD, O.S.B., L.R.C.S., M.R.C.P., under the title *Medical Proof of the Miraculous*.<sup>12</sup> It is almost entirely concerned with Lourdes, where Dr. Le Bec holds an official position. Dr. Ernest E. Ware, senior surgeon, Hospital of SS. John and Elizabeth, London, has written a brief introduction for the English edition.

In the footnote to the notice of the *Annals of Medical History* published last week (p. 383) it should have been stated that Messrs. Baillière, Tindall, and Cox are the English agents and that the annual subscription is £2 2s. post free.

<sup>12</sup> *Medical Proof of the Miraculous: A Clinical Study*. By E. Le Bec, Honorary Surgeon to St. Joseph's Hospital, Paris. Translated from the French by Dom H. E. Izard, O.S.B. L.R.C.S., M.R.C.P. London: Harding and More, Ltd. 1922. (Cr. 8vo, pp. xv + 128. 6s.)

# A CONTRIBUTORY HOSPITAL SCHEME.

WE have received the following letter, dated February 26th, from Major P. A. S. Crawley, chairman of the Sussex Provident Scheme for Hospital and Specialized Medical Services (4, St. George's Place, Brighton):

Since you first drew attention to the Sussex Provident Scheme, a little over two years ago, a number of similar contributory schemes have been established all over the country, and it may interest some of your readers who are connected with the other organizations to learn how the Sussex Scheme has fared during the past year.

The Group Scheme started on April 1st last year and has proved a great success. The number of co-operating hospitals has increased from nine to eleven, but the administration remains in the hands of a neutral body not connected with any particular hospital, and not seeking representation upon the boards of management of the hospitals. The membership—that is, 4,200 subscribers, and those of their dependants who are beneficiaries under the scheme—amounts now to over 10,000, and is rapidly increasing.

Although in two cases during the year we have had to pay a hospital over £60 for one member, we have been able to pay every co-operating hospital in full the out-of-pocket cost of their services to our members, based upon the average cost of such services in the year 1921, with the result that since the scheme has been in existence none of our members has depleted the charitable funds of any of the co-operating hospitals of one penny.

With regard to the hospitals not co-operating with us, we are unable to deal direct, and can only repay our members such charges as may have been made to them, but our co-operating hospitals have agreed that when presenting themselves for treatment with their card of membership, and a letter of recommendation from their private doctor, our members shall not be subjected to any almoner's inquiry as to their means or asked for any contribution for their maintenance or treatment while attending the hospital, the bill being subsequently sent to the committee of the scheme by the hospital for payment.

We have sustained a great loss in the death of Viscount Selby, who was our honorary secretary, and to whose disinterested service the success of the scheme is mainly due.

I enclose the balance sheet of the year's working.

The document to which Major Crawley refers as the balance sheet may perhaps be more accurately described as a statement of receipts and expenditure for the period January 1st to December 25th, 1922. This document may be summarized as follows:

Receipts.		£	s.	d.
Subscriptions:				
Individual Scheme	...	419	7	6
Group Scheme	...	1,501	4	0
		1,920	11	6
Less received in advance for 1923	...	654	14	0
Total subscriptions, 1922	...	1,265	17	6
Add interest on deposit account	...	9	9	5
		£1,275	6	11
Expenditure.		£	s.	d.
Payments to hospitals	...	1,010	17	0
Other payments	...	55	7	0
Administration	...	159	5	10
Sundries	...	4	13	6
		£1,230	3	4

Leaving a balance on the year's working of £45 3s. 7d., which, added to the amount brought forward from 1921, £54 12s. 5d., gives the total balance in hand and carried forward £99 16s.

The statement does not make it clear whether there are any liabilities outstanding against this, nor does it appear by what asset this balance is represented.

<sup>9</sup> *The Yearbook of the Universities of the Empire*, 1922. Edited by W. H. Dawson, and published for the Universities Bureau of the British Empire. London: G. Bell and Sons, Ltd. 1923. (Cr. 8vo, pp. x + 612. 7s. 6d. net.)

<sup>10</sup> London: Constable and Co., Ltd. 1923. 12s.

<sup>11</sup> London: Constable and Co., Ltd. 1923. 7s. 6d.

## Pasteur Centenary Celebration in London.

### ADDRESSES ON PASTEUR AS A BACTERIOLOGIST, CRYSTALLOGRAPHER, AND ARTIST.

#### MEETING AT THE ROYAL SOCIETY OF MEDICINE.

The centenary of the birth of Pasteur was celebrated at the social meeting of the Royal Society of Medicine on Wednesday, February 28th. Among the guests received by Sir William Hale-White (the President of the Society) and Lady Hale-White were Count de Saint-Aulaire (the French Ambassador in London), M. Bonzon (French Consul-General), M. Billecocq and M. Marchat (Assistant Consuls), M. Audra (Institut Français), M. André Simon (President of the Alliance Française), M. Leroux (President of the Committee of French Societies in London), and M. Pierret (Chairman of the French Hospital). A number of the delegates at present in London from seventeen countries attending the second Interchange of Health Officials, organized by the League of Nations, were also present, and there were representatives from the various offices of the British Dominions. The Fellows of the Society and their friends were present in such numbers that the Barnes Hall was overcrowded. The British and French flags were draped over the President's chair, and over a portrait of Pasteur in his laboratory which was exhibited on the platform.

Sir William Hale-White, at the outset of the proceedings, read a letter which had been received from the President and secretary of the Academy of Medicine of Paris, expressing good wishes for the success of the celebration, and stating that they had appointed an Associate of the Academy, Sir Almroth Wright, to represent them. The letter went on to say that the Academy was deeply grateful to the Royal Society of Medicine for rendering this homage to the great Frenchman. "The bonds which unite to-day French science and thought with British science and thought are very strong, and the mutual affection between the two countries is so cordial that every celebration of a great man, be he of one or other nation, is sure to evoke on either side of the Channel the same enthusiasm. Therefore France and Great Britain will march proudly hand in hand for the glory of science and the benefit of humanity."

Three addresses on different aspects of Pasteur's life and work were then delivered. Sir William Hale-White spoke of Pasteur in relation to medicine; Professor T. M. Lowry, F.R.S., on Pasteur in relation to chemistry; and Dr. Gustave Monod, delegate of the Faculty of Medicine of Paris, on Pasteur as artist. Dr. Monod presented to the Royal Society of Medicine for its library a portfolio of reproductions of portraits done by Pasteur as a youth, published in Paris in 1910 with the title "Pasteur, dessinateur et pastelliste." Dr. Monod said that he made the presentation as an expression of admiration for the Society and his "everlasting gratitude towards the noble and hospitable city of London." With the kind permission of M. René Vallery-Radot we are able to reproduce on a reduced scale three of the portraits from the portfolio—that of Pasteur's mother, drawn when he was 13 years of age; that of his father, drawn at the age of 16; and that of Constance Parpaudet, a member of a religious community, made when she was 82 years of age and Pasteur 18.

#### PASTEUR IN RELATION TO MEDICINE.

Sir WILLIAM HALE-WHITE, President of the Royal Society of Medicine, said:

Louis Pasteur was born on December 27th, 1822, at Dôle. It was a remarkable time in the history of medicine. Jenner, whose fame was world-wide, was still alive. Laënnec, that prince of observers, had, two years before, published *L'auscultation Médiate*, and the thin, bony man, already marked for death by phthisis, began his first course of lectures at the Royal College of France three weeks before the day of Pasteur's birth. Bright, who became the best known British physician since Harvey, had settled down at Guy's Hospital, where he made his immortal observations. All these four were for a month alive at the same time; the three elders owe their celebrity to having had, to an exalted degree, the faculty of observing the experiments made by nature; the infant just born attained his by observing the

experiments he made himself; but all four were indomitable workers, marvellously accurate observers, and with them all mere doctrines were made to yield to truth.

Pasteur's father was a tanner who had, in the Napoleonic wars, been created a Chevalier of the Legion of Honour on the battlefield. He was fond of reading and had much influence on Louis, who said on the death of his father: "For the last thirty years I have been his first and almost his only interest in life. I owe everything to him." The old soldier was intensely patriotic and impregnated his son with ardent patriotism, which led him in 1871 to return to the University of Bonn the diploma of the honorary degree of M.D.

"The sight of this parchment is now hateful to me, and I feel it an insult to have my name . . . associated with one doomed from henceforth to the execration of my fellow countrymen—that of Rex Guilielmus."

Likewise in 1895 he refused the Prussian Order of Merit.

Pasteur was appointed Professor of Chemistry at the University of Strasbourg in January, 1849, within a fortnight he had fallen in love with the daughter of the rector, M. Laurent, and they were married on May 29th of the same year. She, during the whole of their married life, appreciated that she had become the helpmate of a great genius. When he was working on a problem he became oblivious to the outside world. He once forgot that he had promised to take her to an important festivity; she waited hours, he did not come, but there was no reproach from her. On occasions she had either to send or to fetch him home from the laboratory to his meals; if not he worked on for hours forgetful of time; she shielded him from all domestic worries. She was never jealous of his devotion to science; in the evening she took down notes of the day's work from his dictation, and helped him to state things clearly by asking him for explanations; not only was she an incomparable companion but his best collaborator. That he would have given less to humanity had he married a different wife must be true. The world owed much to Pasteur's wife. Sir William then related how Pasteur was led to study micro-organisms by the observation that the common mould *Penicillium glaucum*, growing in a liquid containing para-tartaric acid, consumed only the dextro-rotatory tartaric acid, leaving the laevo-rotatory untouched.

Pasteur went from Strasbourg to be Professor and Dean of the Faculty of Science at Lille, where alcohol was manufactured from beetroot by fermentation. The father of one of his pupils was in difficulties because sometimes the process turned out badly. The nature of fermentation was not then understood, but Pasteur showed that the formation of alcohol from sugar was a vital process connected with the growth of a specific micro-organism which performed the conversion, and that another specific micro-organism had the property of forming lactic acid from sugar. From Lille he went to the École Normale in Paris, where his laboratory was two attics, and he had no assistant. The studies on fermentation were continued, and he showed that butyric acid fermentation, several diseases of wine, vinegar, and beer were all due to micro-organisms, which he divided into two great classes: aerobes, requiring free oxygen to maintain their life; and anaerobes, capable of living without free oxygen, but able to wrest this element from its combinations with other elements. All this is common knowledge, and it is difficult to put ourselves back fifty years when it was not. Dumas the chemist begged Pasteur to study silkworm diseases, which were then causing thousands of people to be without a means of livelihood. Pasteur went to live in the district, spent five or six years on the subject, showed that there were two diseases, that each was due to a micro-organism, and each was communicable from worm to worm. Having found the cause, it was easy for Pasteur to show how to prevent the malady, and the large poverty-stricken districts were restored to prosperity.

When investigating chicken cholera, a disease of fowls due to a micro-organism, Pasteur discovered that if these micro-organisms were left for a long while in the laboratory to live on a suitable soil they gradually lost their excessive virulence owing to the long exposure to the oxygen of the air. If now fowls were inoculated with these micro-organisms of weakened or attenuated virulence, the birds were made only slightly ill, and, if subsequently inoculated with the virulent micro-organism, showed no signs of disease, although fowls inoculated with the same micro-organism, but not previously inoculated with the attenuated virus, quickly died. He had made the grand discovery that it was possible to attenuate the virulence of a micro-organism outside the body, and that inoculation with the attenuated virus protected against the disease. This doctrine of attenuation of the virus is of fundamental importance in bacteriology and preventive medicine, and its discovery was one of Pasteur's greatest achievements.

Sir William Hale-White then sketched the manner in which Pasteur succeeded in attenuating the virus of anthrax and that of swine fever, and the application of the attenuated virus for the protection of flocks and herds; considering, he said, Pasteur's work on diseases of wine, beer, vinegar, silkworms, chicken cholera, anthrax, and swine fever, it was easy to see the truth of Huxley's remark: "Pasteur's discoveries alone would suffice to cover the war indemnity of five milliards paid by France to Germany in 1870."

Soon after Pasteur began the study of micro-organisms he saw that his work must bear on medicine, for in 1863, in an interview with the Emperor, he assured him that all his ambition was to arrive at the knowledge of putrid and contagious diseases. Pasteur's work on fermentation led him to the conclusion that putrefaction, like fermentation, was due to micro-organisms which were usually derived from the air. Quite early he showed that when urine decomposed to form ammonia a special micro-organism was at work, and that its activity could be inhibited by boracic acid; consequently this acid was successfully used in medicine for this purpose.

He had not any medical qualification, nor any clinical training; nevertheless, to his great delight, he was in 1873 elected by a majority of one vote to the Academy of Medicine. He was a constant attendant, always urging the importance of micro-organisms in disease, always fighting old-fashioned members who denied this.

But the greatest of all the triumphs that followed from his investigations was, unknown to him at the time, evolved in this country. The mortality due to putrefaction of wounds, whether accidental or inflicted by the surgeon, was appalling. But when Lister learnt that Pasteur had shown that putrefaction was a fermentation caused by the growth of microbes, and that these could not arise *de novo* in the putrescible substance, a solution of the problem appeared. He revolutionized surgery by proving that putrefaction after operations could be abolished if the patient's skin, the surgeon's hands, the sponges, dressings, and instruments were all so treated that they had no living micro-organisms attached to them, and also that if micro-organisms were already there, as they often were after injury, the wound would heal without the onset of blood poisoning if they were rendered inert or removed. At the meeting of the International Medical Congress at Copenhagen in 1884 Lister, addressing Pasteur, said:

"Truly there does not exist in the whole world an individual to whom medical science owes more than to you. . . . Thanks to you surgery has undergone a complete revolution, which has deprived it of all its terrors and has increased its efficacy to an almost unlimited extent."

Hydrophobia or rabies, Sir William said, was communicated by dogs or wolves to man by biting. The suffering was dreadful. He had seen people die of it, and could testify that the illness was the most horrible of those with which mankind could be afflicted; untreated it was fatal. The micro-organism was unknown, but Pasteur showed that the virus resided in the nervous system, by injecting an emulsion of the spinal cord of a mad dog into a healthy dog and thereby causing rabies in it which did not show itself for fourteen days. This, then, was the incubation period. He transmitted the disease by inoculation to a rabbit and from rabbit to rabbit until the ninetieth rabbit was reached, and found that by this means the incubation period was reduced to seven days. By suspending in air the spinal cord of a rabbit dead of rabies having this short incubation period he was able, because of the oxygen in the air, to attenuate the virus so that when an emulsion of such a spinal cord was injected into a dog the animal did not suffer from rabies, nor did he get rabies when inoculated with a virulent spinal cord from a mad dog. In other words, the healthy dog had been successfully vaccinated against rabies. In man the incubation period was long; Pasteur inoculated human beings recently bitten by a mad dog with a rabbit's spinal cord containing the attenuated virus having the short seven days' incubation period, and found, to his intense delight, that they did not get rabies. By this treatment, he said, rabies in human

beings bitten by mad dogs and wolves could be prevented if they came for treatment sufficiently soon after the bite. An English commission appointed by Government to investigate the matter reported that he had proved his claim.

Pasteur was a tremendous worker; I have not mentioned the immense labour he spent in refuting the doctrine of spontaneous generation. But he was much more than a worker—he was an enthusiast; when he gave up chemistry he wrote: "I who did

SOUVENIR MEDAL OF THE CENTENARY OF PASTEUR'S BIRTH (SLIGHTLY ENLARGED). The medal is issued by the Association for the Extension of Pastorian Studies (11, Rue de Valenciennes, 17). The portrait was selected by Madame Valéry-Radot (Pasteur's faithful likeness of her father. The object of the Association is to encourage men and women to take up biological research in relation to medicine, agriculture, and industry.

so love my crystals." He rushed about the country in pursuit of his investigations; at the age of 46 he had a cerebral haemorrhage, but doctors' directions that he must work less made no impression; he never attended social gatherings nor theatres, but he fought all who disagreed with him; his friends thought he wasted time on this, but, as Tyndall said: "Pasteur is combustible and contradiction readily stirs him into flame." This was not because he sought personal glorification—he was most modest—but because he must at all costs uphold what he knew to be correct. He was a marvellous experimenter, proving his assertions up to the hilt by simple but uncontrovertible experiments in which he had guarded against every error. He was an implacable critic of his own and other people's experiments. He had the infinite capacity for taking pains and an intuition for devising just the right experiment. If an analogy suggested itself no use was ever made of it until it had been submitted to experimental verification, but facts fell upon his mind like seeds on a fertile ground, and he had a wonderful faculty for discerning their relative importance. He was fond of saying that "In the fields of observation chance only favours the mind which is prepared."

Then, too, he had the magnetism which made others love to work with him and follow his inspirations; he attempted so much that if it had not been for helpers much must have been left undone. He was a genius, a seer, and a prophet, always adding to knowledge, always looking forward to more additions. "Science," he said, "has no nationality because knowledge is the patrimony of humanity, the torch which gives light to the world. Science should be the highest personification of nationality, because, of all nations, that one will always be foremost which shall be first to progress by the labours of thought and of intelligence."

## PASTEUR AS A CHEMIST.

Professor T. M. Lowry, F.R.S. (Cambridge), said:

In the brief time at my disposal I shall attempt only two things: first, to present in outline a picture of the work which won for Pasteur the chemist a place in the ranks of the Immortals; second, to indicate the bridge by which his chemical work is linked to those biological researches which enabled a mere chemist to claim the attention of a society such as that which I have the honour to address. My task has been made easy by Pasteur himself, since rather more than sixty years ago he delivered to the Chemical Society of Paris two lectures which cover precisely the same field as that into which I propose to guide you to-night.

Pasteur claimed that in his work on tartaric acid he was following in the footsteps of three physicists—Malus, Arago, and Biot. Malus, in 1808, had announced the discovery of the polarization of light by reflection—that is to say, that light reflected from a sheet of glass was altered in such a way that the vibrations in one plane entered the glass, whilst the vibrations in the perpendicular plane were reflected from it. The plane which contained the incident and reflected ray was described as the *plane of polarization*. Arago, in 1811, discovered that when a ray of polarized light was passed through a plate of quartz the plane of polarization was distorted, giving rise to beautiful chromatic effects. Biot, in 1812, made the further discovery that this distortion took the form of a uniform rotation of the plane of polarization, but that some plates of quartz rotated this plane to the right and others to the left. He also discovered, in 1815, that a similar rotation of the plane of polarization was produced by many natural products, such as oil of turpentine and solutions of sugar, of camphor, or of tartaric acid.

We now pass on to consider the relation between the geometrical form of the crystal and its ability to rotate the plane of polarized light. A typical crystal of quartz consists of a hexagonal prism capped by hexagonal pyramids. Haily, however, detected the presence of tiny facets on the alternate corners, which made the crystals lopsided or asymmetric; he also found that these hemihedral facets could be distributed in two ways, giving rise to crystals which could not be superposed upon one another, although they could be converted into one another by reflection in a mirror. Quartz crystals could, therefore, assume two different geometrical forms, whilst plates of quartz could rotate the plane of polarization of light in two opposite ways. It was left to Sir John

FIG. 1.—(a) Dextro-rotatory quartz.  
(b) Laevo-rotatory quartz.

to discover the correlation between these facts, and to show that crystals having one geometrical form always rotated the plane of polarization to the right, whilst those of opposite form rotated it to the left.

I now pass on to consider Pasteur's discovery of similar phenomena in tartaric acid. This acid was known in two forms—the ordinary dextro-tartaric acid, which rotated the plane of polarization to the right, and a modification (which Pasteur called *para*-tartaric acid), which possessed identical chemical properties, but was devoid of optical rotatory power. Pasteur found that tartaric acid and its salts all gave asymmetric crystals, like quartz, whilst the *para*-tartrates gave symmetrical crystals. It appeared, therefore, that there might exist a correlation between the asymmetric crystals of the tartrates and the optical rotatory power of their solutions, similar to that which existed between the asymmetric crystals of quartz and the optical activity of solid plates cut from the crystal.

At this stage Pasteur's attention became fixed upon an observation of Mitscherlich's to the effect that one of the salts of *para*-tartaric acid gave rise to crystals of precisely the same type as the corresponding tartrates. When Pasteur investigated this anomaly he found that, contrary to all previous experience, hemihedral facets appeared on the crystals of the optically inactive *para*-tartrate as well as

of its dextro-rotatory isomer. Further examination of this anomaly showed, however, that whereas in the dextro-rotatory tartrate the hemihedral facets were always of one kind, in the *para*-tartrate both types of crystal were formed side by side from the same solution. It appeared, therefore, that when this particular salt was crystallized the *para*-tartaric acid resolved itself spontaneously into two opposite forms of tartaric acid, one of which had been known for nearly a century, whilst the other, its mirror image, was new to science. It is of interest to notice that in no other known case does this spontaneous resolution of an inactive tartrate

FIG. 2.—(a) Dextro-tartaric acid.  
(b) Laevo-tartaric acid.

take place, and that even the two sodium ammonium salts unite to form a double salt above 26°C. It is, therefore, quite possible that Pasteur's life work might have taken a totally different

course if he had begun his work in a tropical instead of in a temperate climate.

Pasteur was a young student at the time when he made this important discovery, and before communicating the results to the Academy Biot insisted that Pasteur must come to him and repeat before his own eyes the decisive experiment. "He provided me," says Pasteur, "with some *para*-tartaric acid, which he had already studied with particular care and which he had found to be perfectly neutral towards polarized light. I prepared the double salt in his presence, using for the purpose soda and ammonia, which he had also wished to provide for me himself. The liquor was left in one of his rooms to evaporate slowly, and, when it had furnished 30 or 40 grams of crystals, Biot asked me to come to the Collège de France in order to collect them and to separate them under his eyes by their crystallographic

FIG. 3.—Racemic acid.

character into right and left crystals. He also asked me to state again whether I could assert that the crystals which I placed to his right would rotate the plane of polarization to the right and the others to the left. That done, he told me that he would do the rest. He prepared the solutions of carefully regulated strengths, and, at the moment when he was about to observe them in the polarimeter, he invited me afresh to come into his room. He placed in the apparatus first the most interesting solution, that which would rotate the light to the left. Without stopping even to make a measurement, he saw, by a single glance at the colours of the ordinary and extraordinary images in the analyser, that there was a strong deviation to the left. Then, visibly moved, the illustrious old man grasped my arm and said to me, 'Mon cher enfant, j'ai tant aimé les sciences dans ma vie que cela me fait battre le cœur.'

The optical rotatory power of quartz is due, as Fresnel had suggested, to a spiral packing of the molecules, and by the kindness of Sir William Bragg I am able to exhibit a model in which the spiral distribution of the atoms of silicon is clearly shown. This spiral structure can be built up in two opposite ways, but when it is destroyed (for example, by melting the quartz) the optical rotatory power vanishes. The asymmetry, then, is in the crystal, but not in the molecules of silica from which it is built up. Tartaric acid, however, displays its optical activity in solution, and we owe to Pasteur the momentous declaration that the molecules of tartaric acid, as well as the crystals, must be asymmetric. Here, again, through the kindness of Sir William Bragg, I can show you a model which illustrates both the spiral arrangement of the carbon atoms in tartaric acid and the way in which these spiral molecules are packed together in an asymmetric crystal.

Just a word in reference to the biological applications of these discoveries. Pasteur called attention to the fact that in the mineral kingdom, and by the artificial operations of

the chemical laboratory, asymmetric molecules are always produced in equal quantities of opposite types, giving rise to optically inactive compounds or mixtures. Nature, however, almost invariably produces optically active products; and all the materials of the living tissue are branded with this symbol of their divine origin. This, then, is the real distinction between the organic and the inorganic, between nature and man, and this "middle wall of partition" Pasteur was the first to break down. It is indeed a remarkable fact that the three methods which to-day enable us to accomplish the final stage in the synthesis of natural compounds, by endowing our synthetic products with optical activity, were all described by Pasteur more than sixty years ago.

One other link between Pasteur's delicate chemical studies and biology may be mentioned. The mould which ferments ordinary tartaric acid has but little action upon its optical isomer. It was therefore possible by fermenting *para*-tartaric acid to destroy the common dextro-rotatory form, whilst preserving the laevo-rotatory isomer. The yeast, trained for countless generations to assimilate dextro-tartaric acid, refuses to ferment laevo-tartaric acid, and turns away with loathing from the unaccustomed food. This phenomenon has been widely extended, and applies not only to humble organisms but to man himself. Thus, whilst one form of asparagin tastes sweet in the mouth, the mirror image has an insipid taste. If, therefore, through some freak of nature the asymmetry of the vegetable kingdom were reversed, whilst leaving that of the animal kingdom unchanged, we too, like the yeast, might starve in the midst of plenty, unable to digest the unaccustomed sugar with its facets at the wrong corners, or to nourish ourselves upon the finest wheat flour containing starch and gluten of the wrong sign.

This, surely, is the real tragedy of "Alice through the Looking-Glass." The bans and cakes beyond the mirror would present a tempting appearance: the toffee and the barley sugar would still attract her; but if she should stretch out greedy hands and grasp them through the mirror, she would be doomed to disappointment. The fats she would be able to digest, and it might still be necessary to warn her to leave the wine decanter alone, since the alcohol has a symmetrical molecule, and would be equally potent from whichever side of the mirror it was derived; but the carbohydrates and proteins would probably "turn to ashes" in her mouth and provide her with little or no nourishment. Even if she should succeed, however, in finding sufficient food, her growth would certainly be arrested by lack of optically active vitamins of the right sign, and death would certainly await her, perhaps the more merciful if not long delayed. Would insulin be of any value to her in the terrible state into which she would inevitably lapse as a result of wandering to the wrong side of the looking-glass? Even the seven happy years that I spent at Guy's have not qualified me to attempt a prognosis, even when as in this case my diagnosis must be accepted as correct. But, greatly daring, I will assert that all the efforts of the Medical Research Council would fail to save Alice, for the remedies that they would prepare on this side of the looking-glass would have no potency in enabling her to assimilate the strange food on the other side of the glass. Alice must begin all over again, and beyond the mirror organize a medical research council of her own. We should recognize them easily, for the wise inhabitants of that other world would know that they could not do better than to reflect "our" choice, and confirm "our" nomination (I speak on behalf of all the inhabitants, both fanna and flora, of our side of the mirror). But they would have some strange habits. Their hair would be parted on the wrong side; they would carry their watches in their right-hand pockets and listen to the beating of hearts on the right side of their patients. In their moments of leisure they would play golf with clubs of an

unfamiliar type, with which they would make magnificent left-hand drives; but their handicaps and their feelings would remain the same, since these things are not altered by reflection in a mirror. They would then manufacture from materials gathered on the other side, suitable and potent remedies for the diseases of that other world; and they would apply these to Alice. At last she would look forward to a cure, but only to meet with fresh disappointment, since the cure would prove to be only a treatment of her disease, for after all Alice herself must undergo optical inversion, limb by limb and molecule by molecule, turning her right hand into a left and reversing the sign of her tissues, as her body passed through the plane of the mirror, before she could fit harmoniously into the framework of the universe beyond. And there at last we may leave her, happy and contented; and enjoying all the good things that life "through the looking-glass" has to offer.

Such, briefly, is the concept which Pasteur places before us as his earliest contribution to natural knowledge; and we cannot but admire the perfect fashioning of the foundation stone upon which in his riper years he built up the splendid monument, which generations still unborn will visit, in order to lay before it a tribute of laurel leaves such as we bear in our hands to-night.

#### PASTEUR AS ARTIST.

Dr. GUSTAVE MONOD, M.R.C.P. Lond., gave a short lecture on Pasteur as an artist, illustrated by reproductions of some of Pasteur's drawings.

Great men, he said, presented themselves for our study under many different aspects, and we had to regard Pasteur as pioneer, professor, advocate, patriot, and believer, and still more intimately in his home. Pasteur was an artist, not only in the usual sense of the word, but also in the sense of the Latin word *artifex*—a man who translated his ideal of beauty into his life's work. From his childhood Pasteur had known how to observe and how to depict what he observed. Twenty of the portraits he made when a boy were published in 1910, in a limited edition, but, excellent as the reproductions were, they could not give the impression of intense life which the originals preserved in the house of Pasteur's son-in-law, M. Vallery-Radot, conveyed. In that house the home of the Master lived again; his furniture, his work table, his books, and his favourite pictures were all there; his whole life was told in pictures—from the portrait of himself as a young man by Lebayle,

HOUSE WHERE PASTEUR WAS BORN IN DOLE (with a commemorative plate above the door).

passing on to the picture by Eberfeldt, and ending with the poignant drawing of the serene face of the great man sleeping his last sleep.

"Arbois," continued Dr. Monod, "is a little town of eastern France at the foot of the Jura; its hills and clear, rapid streams recall the Highlands of Scotland. Taking ourselves back to 1831, we could imagine a band of noisy children coming home along the river bank from fishing. One of them, a boy small for his thirteen years, attracts attention by his thoughtful expression, and the passers-by smile, saying, 'This is Louis, the son of M. Pasteur, the tanner, our young artist.' For Louis Pasteur, without being in any way an infant prodigy, early distinguished himself by his aptitude in drawing. Doubtless, if we possessed his boyhood's exercise books, we should find in the margins more or less unskilful sketches of his comrades taken from life, and, I should wager, caricatures of his first masters, among them naturally that of the teacher of drawing at the school, M. Pointurier; he was a jovial man, not devoid of talent; he drew as naturally as he breathed and allowed his pupil to develop faculties according to their natural bent. But Louis at the age of 13—the age of daring—dared to attempt a real portrait. Ah! if he could fix upon the paper the most familiar, the dearest, the loveliest of faces. . . . His heart tells him that, though the busy grown-up folk will not find time to sit for him, his mother will understand her child. The others have faces that are unknown and difficult; but

the face of his mother is a landscape of which he knows every secret. 'Oh, mamma, you must put on your pretty shawl and your Sunday bonnet!' Here is the portrait; nearly a century has passed over the powder of the pastel, but we see how seriously she played her part. She sits rather stiffly within the rigid folds of her plaid shawl; the

PASTEUR'S MOTHER. (Pasteur del., aged 13.)

perfect order of her coiffure is framed in an impeccable bonnet. At a first glance her features seem rather severe; doubtless the length of the sitting had its effect... but if we look a little closer do not her lips appear a little—very willingly—compressed? Can we not detect a desire to smile—a desire suppressed so as not to discourage her boy who is struggling to do his best? I think so, for in the eye glistens a happy light which sees

a little artist, silent, grave, absorbed in his work, dominated by the creative effort. . . . "Three years afterwards Pasteur, on the eve of leaving for the first time for Paris, tried to catch the features of his father. As you will recognize, there is a certain poignant sadness in this portrait: is it produced by the coming separation, or by a secret uneasiness due to the leaning towards an artistic career of a son for whom he dreamt of a more certain destiny—for his ambition was to see his son a future rector of the college of Arbois! Or is it the bitterness of the ex soldier of the Grande Armée who knows the vanity of glory? 'I can still recall,' said Pasteur forty years later, on looking at this portrait—'I can still recall this sadness of my father.' This drawing is not signed. Doubtless it remained unfinished. In my opinion it is the most impressive of Pasteur's drawings—the technique is more assured, and the analysis remains as moving in its keen, observant tenderness."

Pasteur went to Paris in November, 1838, but he was miserable there, and his father soon brought him back to Arbois. This was a period of crisis, for the voices of Art and Science were calling him at the same time. It was from this period that most of the drawings shown dated. Dr. Monod called attention to the careful observation and minuteness of the detail in the drawings: "Nothing was missed, neither the embroidery of the mayor's collar, nor a detail of his cross of honour, nor the squint which afflicted him." The last pastel bore the date 1842. It was the portrait of Marcou, who afterwards taught geology at Cambridge, Massachusetts. Durant-Groville, who saw this portrait in America, wrote of it: "Many painters awarded medals at the Salon have never drawn or modelled a mouth with such precision. If Pasteur had wished he could have become someone of standing among painters, and—who knows?—perhaps a very great painter." In the year this portrait was made Pasteur entered the Ecole Normale; he had passed through his crisis; he loved his art with passion, but he saw that his duty lay elsewhere. That was not to say, Dr. Monod insisted, that the

artist was dead within him. Throughout his life he was faithful to his interest in painting; he never missed a Salon, and found time frequently to visit great national galleries. At Dresden, for example, his first visit—to the astonishment of his hosts, who awaited him at the laboratories—was devoted to the Museum. Among his intimate friends

were many artists, among them the sculptors Paul Dubois and Perrault, the painters Henner and Eberfeldt. But Pasteur drew no more. Dr. Monod had it from a friend who had passed his youth in daily intimacy with Pasteur that he had never suspected the draughtsman in the scientist, so much had scientific research monopolized his spirit. He remained, however, a being in whom the faculties of observation and imagination predominated. He

PASTEUR'S FATHER. (Pasteur del., aged 16.)

turned first to chemistry; his youthful curiosity drew him to one of the most arid branches of that science, but one in which investigation was carried out solely by the eye—namely, optic chemistry, crystallography. Dr. Monod suggested that his eye was trained for the analysis of crystals by the analytical drawings of his boyhood; he drew the portrait of racemic acid with similar rigorous observation and passionate imagination. "It was necessary to have seen Pasteur at his microscope," wrote Dr. Roux, "to form an idea of the patience with which he examined a preparation; moreover, he examined each object with the same minute care. Nothing escaped his myopic eye, and we used to say in jest that he saw the microbes growing in the media." The study of racemates bridged the gap between chemistry and biology, and with the study of fermentations began the ascent: investigations of wine; silkworm disease; investigations of beer; virulent diseases; virus vaccines; the prophylaxis of rabies. Link by link the artist built and the experimenter forged the chain of genius. The word "genius" recalled to Dr. Monod the recent estimates of Pasteur at the Academy of Medicine (see JOURNAL, January 6th, 1923, p. 37), and he tried to reconcile the different conceptions of his genius. "Pasteur," he said, "soared above concrete experience. Without imagination the scientist would have stopped at experimental facts. Artist, he swept the infinite with a single cast of his line."

PORTRAIT OF A NUN, with the Inscription, "Sœur Constance Parpandet, âgée de 82 ans." (Pasteur del., aged 18)

Sir Humphry Rolleston, in moving a vote of thanks to the three lecturers, said that there was one note in the President's address which must have found a response among many in that audience—namely, the President's estimate of the great extent to which Pasteur owed his success to the devotion and self-forgetfulness of his wife. Many of them, although much smaller men than Pasteur, would be more than ready to make the same acknowledgement. The Royal Society of Medicine was to be congratulated on having seized this opportunity of paying a well deserved compliment to Pasteur's genius. It was pleasant to feel that the society had been able to

reciprocate in this way the gracious courtesy of the Academy of Medicine of Paris earlier in the year when that body held a celebration in honour of Edward Jenner. This year would be distinguished by the two celebrations, the centenary of Pasteur's birth and of Jenner's death, and by the fact that both men were honoured in London and in Paris.

Sir St Clair Thomson, in seconding, said that in his opening speech the President had rightly remarked that science had no frontiers; but although they welcomed science whether it came from one side of the Channel or the other, or from one side of the Rhine or the other, after all, scientific men had their countries, and it was a great delight to have had placed before them in the address of the President the personality of Pasteur as one of the greatest of Frenchmen. The speaker recalled an occasion when he was motoring through the Savoy in company with a French doctor, and the motor car broke down. They were surrounded by a little crowd of village urchins, and to them his friend put a few questions. Addressing a wee child who was not past the primary in school, he asked her who was the greatest of Frenchmen. "Louis Pasteur," she lisped. He added, "Tell me another great Frenchman—a soldier." "Napoleon," was the answer. "And who was Shakespeare?" "An English poet." The appreciation of great men was a thing to learn from France, and there even the little children were taught that the greatest of Frenchmen was Pasteur.

## RESEARCHES ON ANIMAL NUTRITION AT THE ROWETT INSTITUTE.

### VITAMINS AND MINERAL SALTS.

The first report of the Rowett Institute for Research in Animal Nutrition<sup>1</sup> contains a summary of the very important work which has been done at that institute by Dr. Orr and other workers upon many aspects of animal nutrition. The investigations upon the effects upon farm animals of deficiency of vitamins and of minerals are of special interest to the medical profession.

Most people have probably felt that the continual resort to rats, pigeons, and guinea-pigs, as the subjects of experiments upon vitamin deficiency, is rather unsatisfactory, since these few animals form a very narrow basis upon which to frame any general conclusions as to the importance of vitamins in the economy of animals in general and of man in particular. The animals mentioned are of course subjects of choice because they are inexpensive, easy to keep, and happen to show effects of vitamin deficiency relatively quickly. It is, however, very important to remember that the different species of animals vary enormously in their susceptibility to vitamin lack—for example, deprivation of vitamin C kills a guinea-pig from scurvy within a month, but a rat can live indefinitely on such a diet, although it is soon affected by deprivation of either vitamin A or vitamin B.

Cats, dogs, and human beings are moderately susceptible to vitamin lack, but the report of the Rowett Institute shows that farm animals are remarkably resistant to vitamin deficiency. Their results agree on the whole with those of Sir Arnold Theiler, who found in South Africa that cattle, sheep, goats, horses, and pigs were not affected when fed on vitamin deficient diets for periods of from six to twelve months.

Experiments at the Rowett Institute showed that pigs, when fed on a diet deficient in vitamin C for 124 days, grew perfectly normally, and showed no signs of disease. Deficiency in vitamin A produced no ill effects for about 100 days in young pigs, but more prolonged experiments gave results which suggested that deficiency was producing injury. Young pigs were fed on a basal diet of bran and oats with a little blood meal and mineral salts; one group was given cod-liver oil, and another group an equal amount of linseed oil; the second group were therefore on a diet deficient in vitamin A. Both groups grew normally for 120 days; after this period growth in both groups slowed down, but the linseed oil group stopped growing altogether after 150 days, whilst the cod-liver oil group continued to grow slowly. The authors conclude from this and other experiments that cod-liver oil has a definite beneficial effect on the health and rate of growth of pigs, but that the effect is greatest when the animals are on a diet in which the mineral matter is deficient or ill balanced. Experiments upon lambs gave more definite

results, for in a period of six months lambs given cod-liver oil increased in weight 66 per cent., whereas control animals in which linseed oil was given instead of cod-liver oil only increased 25 per cent. Experiments at Reading<sup>2</sup> upon pigs showed that pigs deprived of vitamin A grew for about seventy days, but that ultimately growth ceased, and signs of defective nutrition appeared. Experiments at Reading also showed that pigs at a certain stage of vitamin deficiency might grow and appear to be in normal health, and yet might be incapable of producing normal offspring.

These results seem to suggest that young pigs and sheep have very low vitamin requirements, but that they cannot thrive indefinitely when the vitamin A supply is reduced below a certain level.

Dr. Orr, however, points out that the vitamin requirements of farm animals are so low that there is very little likelihood of any animal on an ordinary diet suffering from vitamin deficiency. This conclusion is rather important, for it indicates that it is possible for a cow to continue in perfect health when it is receiving so little vitamins that its milk is practically vitamin free. Such a result might be satisfactory to the cow but would not be beneficial to any infant living on its milk.

The researches upon pigs at the Rowett Institute showed that, while their vitamin requirements were very low, yet on the other hand their requirements of mineral salts were very high. It was found that a young pig which puts on about a pound of weight a day could retain about 5 grams each of lime and of phosphorus daily. Moreover, deprivation of minerals in the food produced signs of malnutrition within thirty days.

Rickets is a common disease in young pigs, and experiments showed that deprivation of a proper supply of mineral salts regularly produced the disease, whereas deprivation of vitamin A did not produce the disease. This last result is, of course, in sharp antagonism to Mellanby's results upon puppies. The report concludes:

"The results of these experiments seemed to show that, in pigs at least, the chief factor in the production of rickets is the lack of proper amount and balance of the mineral matter of the food, and that the beneficial influence of fat-soluble A and sunlight on mineral metabolism is most marked in cases where the mineral balance of the food is defective. It is probable that rickets in children is to some extent due to the same cause as the disease known as rickets in pigs. The disease usually comes on between the age of six and eighteen months, which is the period when the child is being weaned on to foodstuffs derived largely from cereal grains. These refined products are even more deficient in essential minerals than the grain and offal fed to pigs."

There is general agreement that deficiency of vitamin A, lack of mineral matter in the food, and lack of sunlight, are all factors in the production of rickets in children. The experiments of the Rowett Institute seem to show clearly that in the pig the lack of mineral matter is the dominant factor in producing rickets. This is to be expected since the pig has a low vitamin requirement and its rapid growth imposes a very high mineral requirement. It does not, however, seem safe to assume that the same will be true of human infants, for these grow at only about one-twentieth the rate of pigs, and the available evidence suggests that man is fairly easily affected by vitamin lack.

The differences between the results recorded above and those obtained by Mellanby in dogs suggest that rickets is produced by different causes in different animals, and therefore it is very desirable to have information as to the mode of production of deficiency diseases in as many different species of animals as possible. Metabolism experiments on large animals are of course only possible at institutes which, like the Rowett Institute, are specially equipped for this purpose, and hence work of the kind under review has a very special value.

<sup>2</sup> Zilva, Golding, Drummond, and Coward, *Biochem. Journ.*, xv, p. 427, 1922.

THE report of the Inchcape Retrenchment Committee has been published in India, but copies have not yet reached this country. The total saving contemplated appears to be nearly thirteen millions sterling, of which over half is to be obtained by a reduction in military expenditure. It is stated that the Committee proposes to abolish the office of Director of Medical Research and to hand over the duties to the Director of the Kausali Institute, and to abolish also the office of Sanitary Commissioner with the Government of India. Comment must be reserved until the text of the report is received.

## British Medical Journal.

SATURDAY, MARCH 10TH, 1923.

THE RECRUDESCENCE OF EPIDEMIC  
KALA-AZAR IN ASSAM.

KALA-AZAR is little known except by name to the profession in this country, and occurs only sporadically in most parts of India; but it is endemic in Assam, where it occasionally becomes epidemic. It is a very serious disease, characterized by splenic, and often hepatic, enlargement, accompanied by subacute or chronic fever and progressive wasting and anaemia. It is due to infection by *Leishmania donovani*, which lives especially in the endothelial cells of blood vessels and lymphatics, and is particularly numerous in the spleen, the liver, and bone marrow; it, however, occurs also in other organs including the mesenteric lymphatic glands, and in ulcers of the intestinal mucous membrane. After a rapid onset with high fever a chronic condition commonly ensued, and though the patient might survive for months the mortality was very high. Though the parasite has been identified the method of infection is still unknown, but the fact that it can be cultivated into flagellate form indicates that this is part of the life cycle. It is thought possible that it is carried by some biting insect, or that when it is excreted in the faeces and gets into water it may be ingested by some aquatic arthropod in which it passes another stage.

The terrible epidemic of the disease which spread up the Assam valley in the last two decades of the nineteenth century culminated within ten years, but not before it had caused the loss of one-third of the inhabitants and a decrease by two-thirds in the area of cultivated land in the Nowgong district. After being long quiescent the disease became active again in 1917 in the division of Sibsagar in Upper Assam, previously uninfected; in 1919-20, for some unknown reason, an extensive recrudescence took place throughout all the districts previously decimated by the disease. Fortunately, however, the value of segregation in stamping out the disease on tea gardens had in the meantime been demonstrated by Rogers and Dodds Price, and the remarkable curative properties of antimony tartrate, which reduced the mortality from 96 to about 10 per cent., had been established. The Public Health Department, under the energetic Sanitary Commissioner of the Province, Lieut.-Colonel McCombie Young, I.M.S., was therefore able, with the help of liberal grants from the Assam Government, to deal much more effectively than was formerly possible with the threatened devastation of the important tea districts of Sibsagar and Dibrugarh; the results of the measures taken have been recorded by Young in a recent paper read before the Assam Branch of the British Medical Association.<sup>1</sup> With the help of a staff of assistant and subassistant surgeons, special kala-azar hospitals, outdoor dispensaries, and out-centres for detecting early cases have been established throughout the province. The Sanitary Commissioner himself has superintended the work on the spot throughout the cold weather touring season, and has in many instances been able by his personal influence and action to detect, isolate, and cure the earliest cases in newly affected villages in a way that was formerly impossible, for the onset of the disease is insidious. The striking result has been that of 36 villages where the first case was detected and dealt with, in 28 no further cases occurred in the following year, and that in nearly two-thirds of 66 villages in which the dread

disease was discovered before the cases exceeded 5 no cases occurred in the following year; on the other hand, in 14 villages in which 5 cases were found when the disease was first discovered only one was free in the following year, and in nine of the remaining thirteen the new cases in the next year numbered from 11 to 30. These facts show clearly that, unless the first few cases are detected by an efficient organization, serious loss of life and not rarely decimation of the village will ensue and great expense will be incurred in segregating the people of the new severely infected villages. The success of the hospitals and dispensaries has been remarkable; during 1920 and 1921 over 32,000 cases have been treated with prolonged courses of antimony tartrate given by intravenous injections. It is estimated that in this way a direct saving of 23,000 lives has been effected, and that, in addition, a much larger number of new infections has been indirectly prevented; this is a wonderful record in a country so medically backward. By this policy it has so far been just possible to keep the renewed epidemic in hand, but the danger is still far from being over.

In the face of these facts it hardly seems credible that the Assam Government should have suggested as a measure of economy the abolition of the post of Sanitary Commissioner of the Province, and that all the work of that officer should be handed over to the already overburdened civil surgeons, who cannot possibly spare the time necessary for the prolonged touring involved in carrying out the kala-azar preventive work of the Public Health Department. The proposal has, however, recently been made.<sup>2</sup> We strongly protest against a policy so penny wise and pound foolish. Anyone personally acquainted with the conditions during the epidemic in the Nowgong district thirty years ago is aware that the result must be untold suffering and loss of life, as well as eventual decrease of land revenue many times as great as the proposed immediate economy; the suggestion could only have been made because the generation of officials has passed away who had experience of the appalling epidemic of three decades ago, when the dead remained unburied, calling to mind the horrors of Russia of to-day.

LUNACY LAW AND THE TREATMENT  
OF THE INSANE.

Dr. J. R. LORD, medical superintendent of Horton Mental Hospital, has recently drawn attention to some of the defects in English lunacy law. He shows that while the Lunacy Act of 1890 was most carefully and conscientiously framed from the local point of view as a measure designed to secure the best treatment of the mentally unsound, it is extremely incomplete. It portrays almost entirely the legal attitude of mind to the insane. The "patient" it deals with means every person received or detained as a lunatic or taken charge of as a lunatic; he is not a "patient" in the medical sense. It is not the onset of disease which makes him a "patient" but an act under the law. It is not the cessation of disease which occasions him ceasing to be a "patient" but the failure to find sufficient cause for detention. To the medical view of insanity a secondary importance is assigned, and respect for the liberty of the subject is accounted of more importance than that those who are afflicted with mental disease should have every opportunity of obtaining the best treatment at the earliest possible moment, and under the most favourable circumstances for their recovery. In effect, the attitude the law takes to a person suffering from mental disease is that he shall not enter an asylum for treatment unless circumstances force it, nor shall he remain there if it is

<sup>1</sup> See p. 179 of this week's SUPPLEMENT.<sup>2</sup> Indian Medical Gazette, February, 1923, p. 75.

possible for him to be outside. Nowhere, Dr. Lord goes on to point out, does the law urge upon citizens the duty of taking prompt steps for the proper treatment of the mentally afflicted; on the contrary, it treats such steps with suspicion and imposes restrictions, with the result that those primarily concerned avoid invoking the law's aid. Dr. Lord considers that the lunacy law wants "completing," as it were, at both ends, in order to cover more appropriately and effectively the early stages of mental disease and the convalescent period. He suggests also that much of it needs recasting to bring it more into accord with the spirit of the time.

A number of factors thus act as barriers to the adequate treatment of the psychoses in their early and more curable stages. The irksome legal restrictions, the abnormal attitude of the patient, the resistances of the relatives, and the reluctance of the doctor—all combine to prevent early and effective treatment. In no form of illness is hospital treatment and removal from the home environment more desirable in the interests of all concerned than in mental disorder; and yet such measures are usually only undertaken when the conduct of the patient renders them imperative. It has to be admitted that there is undoubtedly a "stigma" attached to an ex-mental hospital patient, and the relatives are placed in a very difficult position when the question of certification arises. If treatment in mental hospital be avoided the condition of the sufferer may become hopeless; by adopting it, a life may be partially wrecked. It is this "stigma" which, in Dr. Lord's opinion, constitutes the real difficulty, and he suggests that only a bold attempt to teach the rising generation better ideas regarding insanity will remove it. He advocates the inclusion of a course of mental and physical hygiene in the educational code schools, and considers that if more enlightened notions were to prevail generally among the community most of the troubles regarding the treatment of mental diseases would disappear. It would not matter where a patient were treated or what the institution was called so long as the most effective treatment was secured. Very little is to be said in favour of home treatment, especially in the case of the poor. Home treatment would, in fact, never be dreamt of had people confidence in mental hospitals; the main problem is to discover how such confidence can be gained.

Towards the solution of this problem Dr. Lord makes a number of useful and practical suggestions. He urges that mental hospitals should, as far as practicable, be thrown open in the same spirit as are general hospitals; that they should be part and parcel of the everyday life of the community, and not an exerescence hidden away from the public eye; that social visitors should be appointed; that asylums should be free to experiment, expand, evolve, and progress with the general advancement of medicine like general hospitals; that out-of-date institutions should be abolished and replaced by smaller mental hospitals of modern type; and that there should be better provision in all mental hospitals, preferably in detached buildings, for the treatment of voluntary boarders and incipient insanity—to permit this the law must be altered.

## A STATISTICAL STUDY OF SUICIDE.

THE second number of the Monographic Series issued by the *American Journal of Hygiene* is a thorough study of the statistics of suicide by Dr. John Rice Miner of the Department of Biometry and Vital Statistics in Johns Hopkins University.<sup>1</sup>

In the first section of the monograph international comparisons of rates of suicide are made; particular

attention is devoted to seasonal distribution. In all the European countries (except Switzerland, 1889-1893) the maximum rate is in May or June. There is no obvious connexion with geographical latitude; the statistics of Japan for 1888-1892 show a maximum in May, but a nearly equal incidence in July; for the period 1896-1905 the relations are reversed, the July peak is the taller. In New York City, 1871-1912, the maximum rate was in May. The distribution of suicides by days of the week is shown for Prussia and for the United States. We are a little suspicious of these data. Thus, while in 1907 Prussian female self-destroyers showed a distinct preference for Thursday as the fatal day, no such peculiarity is found in the data of 1908. Dr. Miner suggests that the distributions are probably based upon too few cases to be significant. The total number for both sexes and the two years is 15,133, but the greater proportional frequency of suicide in men may result in the numbers becoming really small for the female experience. In the United States both men and women prefer to kill themselves on Sunday or Monday, particularly Monday. Dr. Miner remarks that "it is conceivable that the greater proportion of suicides on Sunday in the United States than in Europe may be due to the lesser opportunities for Sunday recreation in the former"; it is certainly conceivable—it is also conceivable that the author is experimenting in the ironical. Dr. Miner then confronts the statistics of suicide ordered by the religious confession of the victims. "In the various cases," he writes, "we see exemplified the same law: the conservative and authoritarian cults show lower suicide rates than the liberal denominations. We find this even among the various divisions of Protestantism, where, as in Hungary, they are given separately; the Evangelical church shows a lower rate than the Reformed or the Unitarian. The rapid increase in the Jewish rate accompanies a decay of the influence of orthodox Judaism. These are all further examples of the effect of the group spirit on suicide which we have already seen in the increase of the suicide rate during the nineteenth century and in its decrease during wars." Dr. Miner then deals with sex, age, and occupation. In the tabulation of Ogle, which, however, relates to forty years ago, medical practitioners suffered a very high rate of suicide, being exceeded only by soldiers and those connected with the supply or sale of alcoholic drinks. As might be expected, the choice of means of self-destruction is dependent upon opportunity. Thirty-five per cent. of suicides in the army (Ogle's data) were by gunshot; 60 per cent. of suicides amongst medical men were by poison, 86 per cent. of suicides amongst chemists and 85 per cent. amongst photographers were by the same means.

The second half of Dr. Miner's monograph is devoted to a very careful analysis, with the help of the method of correlation, of the relation between the suicide rate and a number of climatic and demographic factors in cities of over 25,000 inhabitants within the United States Registration Area in the years 1909-11. He reaches the following conclusions: "The net correlations of suicide with mean per cent. of sunshine, altitude, mean temperature, industrialization, and number of negroes are not significant; those with precipitation, age, density, and general mortality are low, but possibly significant, high suicide rates being associated with low precipitation, density and general mortality, and high mean age. The correlation of suicide with proportion of males is  $0.41 \pm 0.04$ ." He states also that "the fundamental factors underlying differences in suicide rates are probably (1) difference in strength of the group spirit, (2) adverse economic changes, (3) racial factors, (4) health of population." A full bibliography is appended, making the monograph as complete a study of a depressing but important subject as we are likely to see.

## THE OLD ENGLISH HERBALS.

He must be a very hard man in whom the word "garden" does not awaken some pleasant memory. Bacon was not tender-hearted, but he wrote: "God Almighty first planted a Garden. And indeed, it is the Purest of Humane pleasures. It is the Greatest Refreshment to the Spirits of Man; Without which, Buildings and Palaces are but Grosse Handy-works." The veriest Cockney, to whom most of the herbs in Miss Rohde's book are nothing but names, may read with pleasure that "Violet is a lytyll herbe in substaunce and is better fresshe and newe than when it is olde. And the floure thereof smellyth moost. . . And the more vertuous the floure thereof is, ye more it bendyth the heed thereof downwarde. Also floures of spryngynge tyme spryngeth fyrste and sheweth somer. The lytylnes thereof in substaunce is nobly rewarded in gretnesse of sanour and of vertue" (a fourteenth-century translation of Bartholomew). Master Gerard's garden in Fetter Lane is gone; none may lease a garden (two acres) east of Somerset House for four pence a year; nor gather the yellow-flowered figwort "in the moist meadowes as you go from London to Hornsey"; but violets may still be had—in bunches and not very "fresshe and newe"—within the Bills of Mortality. Miss Rohde has traced the story of our English Herbals from Anglo-Saxon times to the eighteenth century, from the *Leech-Book of Bald* to the work of John Archer (1673). She is not a "superior" person, but that much more gracious being, a scholar. "Many of us," she writes, "miss all that is most worth learning in old books through regarding anything in them that is unfamiliar as merely quaint, if not ridiculous. This attitude seals a book as effectually and as permanently as it seals a sensitive human being. There is only one way of understanding these old writers, and that is to forget ourselves entirely and to try to look at the world of nature as they did. It is not 'much learning' that is required, but sympathy and imagination." So she is able, with the help of the old books, to conjure up a picture of the days when both men and beasts were often elf-shot and and one fashioned a salve for flying venom from a "handful of hammer wort and a handful of maythe (camomile) and a handful of waybread (plantain) and roots of water dock." We have more modern defences against "the on-flying things," but not—in the case, let us say, of an influenza—always more efficacious. But we do not know that the picture is an attractive one; we are rather of the mind of Johnson in his rejoinder to Monboddo. Our imagination is haunted, not by the romantic beauty of those days, but by the sense of fear which, as R. L. Stevenson said, is master of the primitive mind.<sup>1</sup> "Go on Thursday evening when the sun is set where thou knowest that helenium stands, then sing the Benedicite and Pater Noster and a litany and stick thy knife into the wort, make it stick fast and go away; go again when day and night just divide; at the same period go first to church and cross thyself and commend thyself to God; then go in silence and, though anything so ever of an awful sort of man meet thee, say not thou to him any word ere thou come to the wort which on the evening before thou markedst; then sing the Benedicite and the Pater Noster and a litany, delve up the wort, let the knife stick in it; go again as quickly as thou art able to church and let it lie under the altar with the knife; let it lie till the sun be up, wash it afterwards, and make it into a drink with bishopwort and lichen off a crucifix; boil it in milk thrice, thrice pour holy water upon it and sing over it the Pater Noster, the Credo, and the Gloria in Excelsis Deo, and sing upon it a litany and score with a sword round about it on three sides a cross, and then after that let the man drink the wort; soon it will be well with him." We should justly incur Miss Rohde's censure were we to call this prescription either quaint or ridiculous; rather is it an

illustration of the gloom and dread by which the minds of the people of those days were haunted. Miss Rohde says, truly enough, "suburban life has separated the great concentrated masses of our people from their birthright of meadows, fields, and woods; of Nature, in her untamed splendour and mystery, most of them have never had so much as a momentary glimpse." But with that untamed splendour has gone a heavy burden of fear. As Miss Rohde brings us nearer to modern times there is more beauty and less horror in the lore of plants, and she explains why Gerard's *Herball* has secured an immortality denied to other and intrinsically better books. It is the same reason which keeps Isaac Walton's memory green. Gerard could write. We may conclude our notice of Miss Rohde's pleasant book with a short proof that Gerard could write: "The Plant of Roses, though it be a shrub full of prickles, yet it hath become more fit and convenient to have placed it with the most glorious flowers of the world than to inserte the same here among base and thornie shrubs; for the rose doth deserve the chiefest and most principall place among all flowers whatsoever, being not only esteemed in his beautie, vertue, and his fragrance and odoriferous smell, but also because it is the honor and ornament of our English Scepter, as by the conjunction appeereth in the uniting of those two most royal houses of Lancaster and Yorke. Which pleasant flowers deserve the chiefest place in crowns and garlands."

## VITAL STATISTICS OF HOLLAND IN 1920.

THE *Statistiek van de Sterfte over het Jaar 1920* of the new series of *Bijdragen tot de Statistiek van Nederland* may be compared with our own vital statistics, although, owing to differences of age grouping, this is not always easy. The census population of Holland in 1920 was 3,410,262 males and 3,455,052 females. The proportion of females to 1,000 males was 1,013. In the census population of England and Wales, 1921, the proportion was 1,095. Holland was not a belligerent country, and the constitution of her population in 1920 was not unlike that of England and Wales before the war, and somewhat more favourable to low rates of mortality than ours, as it included a larger proportion of males of military age. The crude death rates were 12.09 for males and 11.66 for females; in 1913 the rates were 12.61 and 12.01. The corresponding rates for England and Wales were 13.4 and 11.5 in 1920, and in 1913 14.7 and 12.8. The infant mortality in the first year of life per 1,000 live births has fallen from 104.3 in 1909-13 to 72.8 in 1920. The mortality in England and Wales fell from 108 in 1913 to 80 in 1920. The difference between the rates in the provinces was very great. For instance, the rate for Noordbrabant in 1920 was 112.6, in Friesland 49.4, and in Noordholland 52.7. Holland has notifications of stillbirths and the vital statistics of infancy are elaborately tabulated. The per mille ratio of stillbirths to all births has not varied substantially since 1910 (37.6 in 1910-19 and 37.4 in 1920). A great contrast is shown in the deaths from infectious diseases in the two countries. England and Wales is only superior to Holland in its death rate from typhoid. In 1920 the crude rate for Holland was 4.6 per 100,000, and the rate for England and Wales only 1.4. On the other hand, the Dutch figures for diphtheria and croup were 7.37, less than half the England and Wales rate of 15. Fifty years ago, 1870-74, the death rate from diphtheria and croup in Holland was 41.14, and the rate for England and Wales 30.5 (1871-75). In the quinquennium 1895-99 the Dutch figure dropped from 33.52 in the previous quinquennium to 17.01, and has remained below that figure up to 1920. The English figures in 1891-95 were 32.3 and in 1895-1900 30.7. Scarlet fever mortality in Holland was 1.84 in 1920 and 5.39 in 1919. The corresponding figures for England and Wales were 3.8 and 3.3. The death rate from measles in Holland was 9.21 in 1920 and 19.1 in England and Wales. The rates of mortality for all forms of pneumonia were 14.03 per 10,000 males and 12.12 for females, and in England and Wales 12.06 and 7.78. The death rates from tuberculosis show a very

<sup>1</sup> *The Old English Herbals*. By Eleanor Sinclair Rohde. London: Longmans, Green, and Co. 1922. (Cr. 4to, pp. xi + 243; illustrated. 2s. net.)

<sup>2</sup> "For it is scarce possible to exaggerate the extent and empire of his superstitions; they mould his life, they colour his thinking; and when he does not speak to me of ghosts, and gods, and devils, he is playing the dissimular and talking only with his lips." (*In the South Seas*, Part II, Chapter VI.)

high mortality for women, 11.84 per 10,000 females against 10.02 for males. In 1901-05 the male rate was higher than the female—13.77 and 13.31. The crude rates for England and Wales in 1920 were 10.15 males and 7.75 females. Comparing the female death rates at ages in the two countries, the rates of Holland are in excess of the English rates at every age group, and especially at the early and later ages. If the rates of Holland are expressed as a percentage of the English rates, at all ages over 50, the Dutch women die from tuberculosis at 205 per cent. of the rate for the English women, and 272 per cent. at ages under 1 year. The mortality rate from all forms of cancer was 11.26, almost identical with that of England and Wales, 11.61. In one province only, Limburg, has the rate diminished over the past twenty years. The report suggests that this may be due to the fact that the mining industry has greatly developed there and the constitution of the population by age has become unfavourable to high cancer rates. The most striking feature of the site rates is the more favourable position of Dutch women regarding cancer of the female genital organs and breast, and the higher mortality in Holland ascribed to cancer of the stomach and liver. Roughly speaking, the Dutch rate for the two former sites is little more than half of that of England and Wales, and for the group including stomach and liver more than 60 per cent. higher.

#### BENVENUTO CELLINI.

IN a recent essay on Benvenuto Cellini's diseases and doctors Professor A. Castiglioni<sup>1</sup> remarks that among the biographical documents handed down to us from the sixteenth century none possesses the freshness, spontaneity, and fascination of Cellini's autobiography, which, strange to say, has received more attention from foreigners, such as Goethe, Dumas, and Symonds, than from his fellow countrymen. Like Casanova in his *Memoirs*,<sup>2</sup> which give a vivid picture of social life two centuries later, including much of interest to the medical reader, Cellini describes his illnesses, which included malaria and syphilis, and an account of contemporary medical men and quacks not unfrequently accompanied by scathing criticism of their methods of treatment. Both writers were boastful, unscrupulous, and almost if not entirely destitute of moral sense, but both preserved their mental and physical powers until the end. Cellini's first illness was a malarial infection which he contracted in 1517 at the age of 17 in Pisa, where prior to the extensive hygienic improvements carried out by Cosimo I malaria was rampant. He had a second attack at Mantua in 1528, a more severe one in 1535 at Rome, where he was attended by Francesco da Norcia, one of the most distinguished physicians of the time, and a fourth attack during the casting of the celebrated Perseus statue. During the epidemic of plague in 1524 Cellini was at Rome, where he made the acquaintance of the celebrated anatomist and surgeon Berengario da Carpi, to whom he sold some of his vases. The illness which Cellini contracted at this time was probably not, as he imagined, an attack of plague, but a simple cellulitis of the arm with lymphadenitis due to septic infection of the hand. At the age of 32 Cellini contracted syphilis at a time when the disease was almost endemic. Although no mention is made of a primary lesion, the history of exposure to infection, the occurrence of an eruption and an inflammation of the eyes (specific iritis), which interfered with his professional activities, leave no doubt as to the nature of the affection. He promptly submitted to two courses of treatment—by guaiacum, then known as "lignum," "sanctum lignum," "spes hominum," "gloria novi mundi," which had recently been introduced from America, where the Spaniards had observed that decoction of guaiacum was used for treating various ulcerative diseases of the skin. "Probably no remedy in the history of medicine," says Professor Castiglioni, "has enjoyed a wider, more rapid, and undisputed success." Its efficacy in Cellini's case is shown by the fact that there is

no subsequent mention in the autobiography of any symptoms suggestive of further syphilitic or parasymphilitic manifestations. During his stay in Paris in 1537 Cellini became a firm friend of the celebrated anatomist Guido Guidi, who has given his name to the Vidian artery and nerve, and was at that time court physician to François I. The privations which Cellini underwent during his prolonged imprisonment in Rome in 1538 and 1539 do not appear to have had a permanently injurious effect upon him any more than the imprisonment in the "Leads" at Venice did on Casanova, although he was suffering from a broken leg caused by an attempt at escape, and was living in deplorably insanitary surroundings. An attempt to poison him during his imprisonment by one of his enemies, who mixed powdered jewels in his food, was discovered in time, but a subsequent attempt with sublimate ten years later was more successful; he did not completely recover from the effects for over a year. According to Professor Castiglioni, the charges of homosexuality and sexual perversion which were also brought against his contemporaries Michael Angelo and Sodoma do not rest upon a sure foundation, nor can his frequent quarrels with his fellow artists and others be regarded as evidence that he was suffering from delusions of persecution. The story of his life as told in the autobiography stops abruptly in the year 1562, but he survived another nine years, dying of angina pectoris at the age of 71, in full possession of his faculties. The translation into English by J. A. Symonds, first published in 1887, has truly been called masterly; it is a fascinating book.

#### MILK UNDER SPECIAL DESIGNATIONS.

For several years past milk has been sold as "graded" and "certified" under the provisions of Orders made by the Food Controller and later by the Minister of Health. Since January 1st of this year the sale of milk under these and other designations has been regulated by the Milk and Dairies (Amendment) Act, 1922, and by Orders made by the Minister of Health under that Act. Milk may now be sold under four special designations—namely, "certified," "Grade A (tuberculin tested)," "Grade A," and "pasteurized." In a memorandum issued by the Ministry of Health for the information of those specially concerned particulars are given of the conditions under which these designations may be used and the steps which must be taken to secure authority for their use. The producer of certified milk must obtain a licence from the Minister of Health, for which he has to pay an annual fee of £5. Those who deal in this milk must obtain a licence costing five shillings from the local authority in whose area their trade is carried on. The herd must be tested by tuberculin prior to the granting of the licence and subsequently every six months, and must be examined every three months by a veterinary surgeon nominated by the Minister. The milk must be bottled on the farm immediately after production. The cap of the bottle must form a seal and must bear the address of the producing farm and the day of the week on which it was produced, together with the words "certified milk." At any time before delivery to the consumer the milk must not contain *Bacillus coli* in one-tenth of a cubic centimetre or more than 30,000 bacteria per cubic centimetre. It must not be pasteurized. The regulations with respect to Grade A (tuberculin tested) milk are similar to those for certified milk as regards the testing of the herds and prohibition of pasteurization, and the licensing authority for the producer is again the Minister of Health. Otherwise the production and distribution of tuberculin tested milk is governed by the regulations for Grade A milk. For Grade A milk the council of the county or county borough grants the licence at a fee of one guinea in respect of the farm and two guineas in respect of the bottling establishment, whether at the farm or elsewhere. The distributor is licensed by the local authority, the fee being five shillings. The herd must be examined every three months by a veterinary surgeon nominated by the licensing authority. If the milk is pasteurized the fact must be stated on the cover

<sup>1</sup> *Bollettino dell' Istituto Storico Italiano dell' arte Sanitaria*. November-December, 1922, p. 221.

<sup>2</sup> J. D. Rolleston in *Janus*, 1917, xxii, p. 215.

of the containing vessel; the milk must not contain *B. coli* in one-hundredth of a cubic centimetre or more than 200,000 bacteria per cubic centimetre. The milk must be dispatched from the farm in an unventilated sealed container on which is placed the address of the farm, the day of production, whether produced morning or evening, and the words "Grade A milk." For pasteurized milk a local authority grants the licence for a fee of one guinea in respect of each pasteurizing plant, and of five shillings with respect to each establishment at which such milk is sold. Pasteurizing must not be carried out more than once. The containers must be labelled with the date of pasteurization and with the words "pasteurized milk." After pasteurization there must not be in the milk *B. coli* in one-tenth of a cubic centimetre or more than 30,000 bacteria per cubic centimetre, subject to the provision that, until January 1st, 1924, no test for *B. coli* will be imposed, and the maximum bacterial content may reach 50,000 per cubic centimetre. In an address which Dr. John Robertson, the medical officer of health for Birmingham, recently delivered before a sessional meeting of the Royal Sanitary Institute in Birmingham he stated that average milk when it reached Birmingham contained over 2,000,000 bacteria per cubic centimetre, which meant that it had been milked under more or less dirty conditions, that it had not been properly cooled, and that it had been delayed for a considerable time on its journey to the city. He considered that the cost of producing certified or graded milk was practically prohibitive to the ordinary consumer, but recommended pasteurization on a uniform basis, the pasteurization being controlled. He urged that farmers and dairymen must recognize as essential to the production of clean milk that every article in which milk is received, from the farmer's milking cans to the railway churns and bottles, should not only be cleaned, but subsequently sterilized by steam.

#### SMALL-POX PREVALENCE.

From the returns of the Registrar-General it appears that in the first eight weeks of the year—from December 31st to February 24th—305 cases of small-pox were notified in England and Wales outside London. In the successive weeks the numbers were 12, 48, 46, 48, 37, 27, 41, and 46. The counties chiefly affected have been Derby with 115 cases, the West Riding of Yorkshire 82, the North Riding 43, Notts 39, and Durham 11. Cases have occurred also in the counties of Stafford, Lancaster, Lincoln, Hertford, Hereford, and the Soken of Peterborough. Included in these figures are the towns of Doncaster (60 cases), Middlesbrough (42), Nottingham (12), and Ilkeston (10). The other districts with the largest numbers of attacks are in Derbyshire—Heanor having had 59 cases and Clown 34. At Basford in Notts there have been 15 notifications. The disease appears to be of a mild type. Fortunately the outbreak of a very severe strain of small-pox which attacked the inmates of Poplar Workhouse was stamped out in its limited and well defined area by the concentrated efforts of the several authorities concerned. It has been said that in some parts of America an exceedingly mild type of small-pox has become practically endemic, no doubt owing to its being so lightly regarded in respect of the calling in of medical aid, and of notification, vaccination, isolation, surveillance of contacts, and so forth. What the present position in America is we cannot say, but great vigilance may be required to prevent endemicity of the infection in Britain; and it must never be forgotten that though mild small-pox often breeds true, that is not always the case, and virulence may develop as an outbreak proceeds. It is locally reported that at Clown, where seven more cases have been notified two or three days ago, the disease is taking on an increasingly virulent character. It would be the falsest of false economy if the staff of the Ministry of Health were so starved of personnel as to be unable to give the country the fullest benefit of the unsurpassed knowledge of its medical department in the investigation and control of small-pox. It is said that the disease has appeared in Aberdeen, where the last case occurred in 1918.

#### VISIT OF FOREIGN HEALTH OFFICERS.

The foreign health officers now visiting England and Scotland to study methods of health administration, under the auspices of the Health Organization of the League of Nations, left for the provinces after a strenuous week in London. The party, numbering twenty-nine, is drawn from fourteen European countries, from the United States, and from Japan. By request of the Ministry of Health the arrangements were made by Society of Medical Officers of Health, and it was at the house of the Society that the visitors were welcomed on their arrival by Dr. W. J. Howarth (chairman) and the other members of the reception committee. The occasion offered an informal opportunity for guests and hosts to become known to one another, and Sir George Newman, in a speech of greeting, indicated the great benefits that might be expected to result from the comparative study of methods of health administration in various countries. On the following day (February 26th) the visitors were officially welcomed at the Ministry of Health by the Earl of Onslow, Parliamentary Secretary to the Ministry, and Captain Walter Elliot, M.P., Under Secretary for Health for Scotland. Sir George Newman gave an illuminating address on the whole system of public health administration in England and Wales. In the afternoon and on the following morning explanatory lectures on the various activities of the Ministry were delivered by Lieut.-Colonel S. P. James, Dr. Barbara Cunningham, Dr. F. J. H. Coutts, and Dr. J. Smith Whitaker, so that the visitors started their tour with a good insight into the scheme of central administration. On Tuesday afternoon a visit was paid to the Royal Army Medical College, where the guests were received by the Director-General (Lieut.-General Sir John Goodwin) and the Commandant of the College (Colonel C. B. Martin). An address on "The present-day trend of military hygiene," by Major N. V. Lothian, was followed by a series of demonstrations in the laboratories by the staff of the College. Later the visitors were entertained at tea at the R.A.M.C. Mess, where they had an opportunity of talking with Sir William Leishman, Sir William Macpherson, and a number of civilian guests who had been invited to meet them. The whole of March 1st was spent with the Registrar-General and his staff examining the statistical methods at Somerset House and the compilation of the Census returns. The following day was occupied to great advantage in visiting institutions of the Metropolitan Asylums Board. The system for the collection of fever cases and their allocation to the most convenient hospitals was explained during a visit to a typical ambulance station. An inspection of the Brook Fever Hospital at Shooter's Hill under the guidance of Dr. J. B. Byles was followed by a visit to Queen Mary's Hospital at Carshalton, where Dr. W. T. Gordon Pugh explained the methods of orthopaedic treatment, which greatly interested the foreign delegates. On their way back to London the party were shown round the Tooting Bec Mental Hospital by Dr. E. H. Beresford, and the day closed with a comprehensive account of all the Board's undertakings by the clerk, Mr. G. A. Powell, C.B.E., whose lecture was illustrated by lantern slides. The party was much impressed by the magnitude of the Board's work. On March 2nd it was the turn of the Metropolitan Water Board; after a formal reception by the vice-chairman and other members of the Board, Sir Alexander Houston gave a lantern lecture on the work of his laboratories in connexion with water examinations, and then accompanied the party to the reservoirs, filters, and chlorinating plant at Hampton. The final fixture of the week enabled the party to see something of the housing schemes of the London County Council. Escorted by Lieut.-Colonel C. B. Levita (chairman of the Housing Committee), Dr. William Butler, Mr. David Edwards, and other officials of the Council, they were shown the clearance scheme in the Tabard Street area and the new houses at Roehampton. Throughout the week the visitors have been greatly interested in the programme arranged for them, and in every case they have been supplied with reports and other documents which will enable them to

understand the full significance of what they have seen. Although the visit is not intended to be of a festive nature the guests have enjoyed some pleasant hospitality during the week. On Monday the Royal Sanitary Institute held a reception in their honour, which was attended by the diplomatic representatives of most of the countries that have sent delegates; on Wednesday the whole party attended the Pasteur celebration at the Royal Society of Medicine. In groups of four or five they are now pursuing their course of study at Glasgow, Newcastle-on-Tyne, Liverpool, Manchester, Bradford, and Birmingham, until they return for a second week in London after Easter.

#### THE MEDICAL AND DENTAL REGISTERS.

THE *Medical Register* for 1923 has been issued.<sup>1</sup> From a table prefixed to the list it appears that it contains 46,477 names; of this number 22,713 (48.88 per cent.) are shown as registered in England, 14,605 (31.42 per cent.) in Scotland, and 6,814 (14.66 per cent.) in Ireland. There are 2,239 (4.81 per cent.) on the colonial list, and 106 (0.23 per cent.) on the foreign list. The names newly registered in 1922 numbered 1,984—a larger number than in any previous year, and exceeding the number registered in 1921 by 224. The number of names removed was 1,045; of these, 725 were removed on evidence of death and 311 under Clause XIV of the Medical Act of 1855, which requires the Council to erase from the *Medical Register* the name of any person who failed to reply to an inquiry addressed to him by the Registrar as to whether he has ceased to practise or has changed his address. The volume contains also the warning notices issued by the General Medical Council and by the Dental Board of the United Kingdom. The latter appear also in the *Dentists Register* for 1923, together with the regulations of the Dental Board. Owing to the operation of the Dentists Act, 1921, the number of names on the *Dentists Register* has been more than doubled; the number in the issue for 1922 was 5,831, the number in the issue for 1923 is 12,762. The number added by registration since the last issue is 7,603, and of these only 334 were registered with qualifications. Altogether 712 names were removed; of these 7 were removed for failure to reply to an inquiry, and 636 owing to failure to pay the required fee. The number of dentists with a colonial diploma has risen from 5 to 10, and those with a foreign diploma from 3 to 6. The General Medical Council has also issued a volume containing lists of medical and dental students registered during the year 1922; the total number of medical students so registered was 1,833 and of dental students 424.

#### BRITISH CONGRESS OF OBSTETRICS AND GYNAECOLOGY.

The fourth Annual British Congress of Obstetrics and Gynaecology will be held in Edinburgh on April 19th and 20th, with a possible extension to the 21st. The gathering is really a conjoint meeting of the various obstetrical and gynaecological societies in the United Kingdom and Ireland—namely, the Royal Society of Medicine (Section of Obstetrics and Gynaecology), the Edinburgh Obstetrical Society, the Glasgow Obstetrical and Gynaecological Society, the Midland Obstetrical and Gynaecological Society, the Royal Academy of Medicine in Ireland (Obstetrical Section), the Ulster Medical Society, and the North of England Obstetrical and Gynaecological Society. On this occasion the Edinburgh Obstetrical Society hopes to welcome a large number of representatives from the other societies. The Royal College of Surgeons has kindly granted the use of its hall for the discussions, and the Royal College of Physicians is allowing the use of its hall for a dinner which will be held on the evening of April 19th. The main discussion on the first day of the Congress will be upon intrinsic dysmenorrhoea, regarding the main features of which a report embracing information and statistics from different parts of the country will be pre-

sented. Opportunity will also be afforded for a number of short papers on other subjects, and for the exhibition of specimens of special interest. The secretaries of the Edinburgh Society, Dr. H. S. Davidson, 52, Melville Street, and Dr. James Young, 29, Manor Place, will be glad to receive notice of such papers or specimens as soon as possible. Those who intend to be present are also requested to inform the secretaries either directly or through the secretary of their own society.

#### NORTH PERSIAN FORCES MEMORIAL MEDAL.

We have been asked by the War Office to announce the institution of a Memorial Trust Fund, commemorative of the services of the late North Persian Forces, which has been subscribed by officers of the Royal Army Medical Corps and Indian Medical Service who served with these Forces. In accordance with the desire of the subscribers to encourage the study of tropical medicine and tropical hygiene it has been decided that the Memorial should take the form of a silver medal, to be known as the "North Persian Forces Memorial Medal," to be awarded annually for the best paper on tropical medicine or tropical hygiene published in any journal during the twelve months ending December 31st by any medical officer, of under twelve years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service. The first award will be for the best paper published during the twelve months preceding December 31st, 1923. The award will be announced in the latter part of the year following that in which the paper was published, provided that the Memorial Committee considers the papers published to have attained a standard of merit justifying an award.

SIR RICHARD HAVELOCK CHARLES, Medical Adviser to the India Office and President of the Medical Board, will shortly attain the age limit, but, owing to the exigencies of the service, his retirement is for the present postponed. Statements which have been published with regard to his successor are entirely devoid of foundation.

#### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

##### Dangerous Drugs and Poisons (Amendment) Bill.

THE Home Secretary (Mr. Bridgeman) moved the second reading of the above-named bill on February 28th. He said that at present any constable could enter the premises of any person carrying on the business of a producer, manufacturer, seller, or distributor of drugs and inspect his books. That was inadequate, for while search could be made only of the premises of known dealers in these articles those who carried on the trade secretly were missed. Accordingly powers were asked to search the premises, persons, and papers of any person suspected of being in illicit possession of drugs. The second clause was intended to bring within the penal provisions of the bill acts done in this country with a view to illicit transactions abroad. Enormous profits were made by this trade. In a recent instance it was believed that someone got as much as 2,400 oz. of morphine and 2,500 oz. of cocaine, which represented several million doses. For such an offence a fine of £200 was far from adequate. France had already set the example of increasing penalties, and the Council of the Assembly of the League of Nations recommended the Governments concerned to consider the question of more substantial sentences of imprisonment. Therefore it was proposed to substitute for the existing penalties a maximum of ten years' penal servitude, or a fine of £1,000, or both, in cases of conviction on indictment, and, secondly, a maximum penalty of twelve months' imprisonment, or a fine of £250, or both, in cases tried summarily, and it was proposed to do away with the provision for increasing the penalty for a second offence. In Clause 3 were provisions to meet the difficulty which the Pharmaceutical Society had brought to the notice of the Home Office in regard to the supply of drugs to duly qualified medical practitioners. Under the Pharmacy Act, 1868, there was a "poison book" which everyone was expected to sign on buying these drugs at a chemist's shop, but in practice it was impossible to observe the provision, and he thought it had been largely allowed to fall into disuse.

<sup>1</sup> London: Published for the General Medical Council by Constable and Co., Ltd.

Until the report was presented the Minister could not say whether it would be published. In view of the necessity of placing orders for the printing of cards some months in advance of their issue, it would not now be possible for the proposal for a joint card, if it were recommended, to be brought into operation by July next.

**Expenditure on Health Insurance.**—In a written answer to Mr. Rhys Davies, on February 28th, as to certain particulars of expenditure on National Insurance, Sir W. Joynson-Hicks said that the amounts annually expended in England and Wales out of National Health Insurance funds on the two accounts mentioned were approximately:

1. Provision of medical benefit (excluding drugs) by insurance practitioners ... £6,520,000
2. Provision of drugs and appliances ... 1,280,000

The amounts similarly expended in Scotland were (1) £870,000 and (2) £160,000. Medical benefit was not provided to insured persons in Ireland.

**Tuberculosis Treatment.**—Mr. Rhys Davies asked, on February 28th, the number of persons suffering from tuberculosis who had failed to secure admission to sanatoriums. Viscount Wolmer said that the number recommended for and awaiting treatment in residential institutions from local authorities in England and Wales on February 1st, 1923, was 2,902, on which date 16,393 persons were receiving such treatment, and there was a number of vacant beds. The Minister was not aware of the number of notified cases which had not been admitted to residential institutions; but not all notified cases received or were willing to receive such treatment.

**The Supply of Insulin.**—Dr. Chapple asked, on February 28th, whether, in view of the fact that the cost and scarcity of insulin were depriving many poor sufferers from diabetes of the measure of cure which it was able to provide, the Ministry of Health would make a special grant for its more rapid and abundant production. Viscount Wolmer replied it was not the poor only who were deprived of the advantages of insulin. It could not be made available until a supply of known efficiency, potency, and safety was attained upon a manufacturing scale. Considerable progress had been made by the Medical Research Council, which believed that, subject to limitation of raw material in particular districts, the successful manufacture of insulin in the near future was assured. No special grant-in-aid would accelerate the production at this stage.

**Pasteurization of Milk.**—Mr. Hope Simpson asked, on February 28th, whether the provisions of the Milk (Special Designation) Amendment Order, 1922, now lying on the table at the House, required employment of a plan for pasteurization, the expense of which was beyond the means of the smaller retail dairymen; and whether the application of this Order would tend to increase the power of the milk combine. Viscount Wolmer replied that some such representations had been made to the Minister, but he did not regard them as sufficient to justify a departure from the principles on which the Order had been made. "Pasteurization" was a designation applied to milk which had been subjected to certain heating processes as set out in the Order. Such processes could not be undertaken except by the adoption of the necessary means or machinery entailing some capital expenditure. There was nothing in the Order to compel any dairyman to pasteurize the milk he offered for sale.

#### Answers in Brief.

Approximately 3,000 ex-service men were at present receiving residential treatment in institutions for tuberculosis. The average cost of treatment was £2 17s. 6d. a week for each patient, and, in addition, treatment allowances averaging £2 a week for each patient were paid by the Department.

According to the annual returns 3,555 persons were proceeded against for alleged offences in the adulteration of food, drugs, etc., in 1921. Of these, 2,329 were convicted. In 1922, 2,400 persons were proceeded against, and of these 1,586 were convicted. These figures were provisional only.

Viscount Wolmer has stated that a medical officer of the Ministry of Health, who is about to visit Northumberland, will report on the disability of insured inhabitants on Holy Island owing to the fact that no doctor resided there.

In the cases of the ex-service men whose insanity had been adjudged not to be due to military service, there have been 328 appeals, of which 225 have been heard. Of these 77 have been decided in favour of the men.

If the existing system of taxation of income were so altered that the income of married persons were taxed separately, it is estimated that the immediate loss to the Exchequer would be £12,503,000, and the ultimate loss approximately £35,000,000.

The Home Secretary has stated that the Home Office Committee which dealt with compensation for industrial diseases had reported that there would be great difficulty in bringing pneumoconiosis under the Act, and

was passed to enable the different lines. He had received the working of the scheme.

Sir W. Joynson-Hicks has stated that the effect of the report of the medical officer of health for the West Riding of Yorkshire, dealing with the condition of cowsheds in the administrative area, appeared to be that the existing law was not satisfactorily enforced in the county by reason of the small amount of inspection carried out by the district councils who were responsible for its enforcement. Under Section 11 of the Milk and Dairies (Amendment) Act, 1922, the county council could apply to the Minister of Health to transfer to it the powers of any defaulting district council.

Of the 977 voluntary boarders resident in licensed houses and registered hospitals for mental patients during the year 1922, in the first named 85 were detained and certified and 3 were certified and sent to other institutions; in registered hospitals 57 were detained and certified and 5 were certified and sent to other institutions.

#### An Address

ON

### RELIGION AND SOME MEDICO-SOCIOLOGICAL PROBLEMS.

DELIVERED TO THE MARYLEBONE DIVISION

BY

THE DEAN OF ST. PAUL'S.

At a largely attended meeting of the Marylebone Division of the British Medical Association on March 2nd the DEAN of ST. PAUL'S (the Very Rev. W. Ralph Inge, D.D.) gave an address.

The DEAN said that when he was honoured with the invitation to address that gathering it was suggested that he might take one of those subjects which were interesting alike to the physician of the body and the physician of the soul. A closer co-operation between the medical and the clerical professions had long been a matter very near to his heart. There were so many respects in which the work of the two professions overlapped or even coincided, and with knowledge and goodwill the clergy and medical men might be brought closer together, to the great benefit of mankind.

#### Mental and Spiritual Healing.

It was very necessary that religion should become scientific, and that science should cease to be—if it ever was—materialistic. Nevertheless, when one left generalities of that kind, the difficulties of the position became obvious. There were in evidence, for example, various methods of faith healing, from Christian Science to the creed of M. Coué; it was difficult to say how far these methods had any scientific value. Before the war he was a member of a committee sitting at Westminster, composed half of clergymen and half of doctors, the object of which was to investigate the methods of mind cure and faith healing which were advertised or followed. When the committee examined those who professed to work miraculous cures by religious means his own impression was far from favourable. It seemed to him that not only did their evidence break down, but their whole attitude was unsatisfactory. The committee had just begun on Christian Science—whose advocates were very ready to furnish it with information—when the war broke out, and the committee had had no further sittings. The only witnesses who impressed him at all were two doctors who had been engaged in treatment by suggestion. They stated that they never attempted to treat any organic disease, but he began to be a little dissatisfied the other way after hearing their evidence, for it seemed to him that they regarded it as a dogma that no organic disease could be successfully dealt with by these methods, and therefore when they cured patients whose cases had been so diagnosed by other doctors they assumed that the diagnosis was incorrect. He could not help pointing out to them that that was exactly what the committee had met to decide—whether treatment by suggestion could benefit organic disease. All were agreed that hysterical and nervous cases were benefited by these methods, and equally that such a thing as a broken leg could hardly be benefited; but there was a large class of intermediate cases, including diseases caused by micro-organisms, about which more evidence was desirable. He wanted to know whether or not the encouragement of the patient and the awakening in his mind of a lively faith that something was going to happen might have some effect, possibly by the production of some kind of hormone, actually to destroy the germs of disease. At all events, of late years the functions of the ductless glands had excited very great interest, and there was still much to learn about their action. When Edward VII, not many years before his death, was in Germany he was found to be suffering from a mild form of diabetes, and a consultation took place, attended by four German doctors and one English doctor. The Germans became so furious with each other as almost to get to blows, and after the altercation had gone on for some time the English doctor said, "Really, gentlemen, I believe that if we took our tests we should find that most of us were suffering from glycosuria." Rather impressed by this idea, the Germans did make the test, and found that three out of the four had sugar. If this could be the consequence of anger, as seemed probable in this instance, it was possible that the awakening of a lively hope in the mind of the patient might have effects not yet determined in the opposite direction.

#### The Storm Centre of Morals.

The Dean then turned to the subject of psycho-analysis. It had been stated that Freud, whom he had never read, had only one idea, and that a nasty one; but he imagined that

there was a great deal more in Freud than that. The vulgarization of psycho-analysis was doing an enormous amount of harm by encouraging young people to think that they had a right to indulge their passions, and that to repress them was bad for health both of body and mind. The special subject on which he was venturing to speak that evening was difficult and delicate, but he thought that no apology was needed for choosing it, for it was really the storm centre of morals at the present time, and it was a subject on which the clergy and all who were not doctors required a good deal of instruction. Some years ago he preached in St. Paul's to a medical congress and hinted that he thought the medical profession had been a little wanting in candour and courage because it had not told the public certain things which the public ought to know. He touched especially on the subject of venereal disease, which at that time was still taboo. He urged that the question ought not simply to be shelved, but should be thoroughly thrashed out and discussed. Since then, of course, the question had been brought out into the open, and newspapers no longer refused to give it publicity.

He did not intend to say much on the question of prophylaxis, which had divided medical opinion, though here one would wish that clergy and doctors should work together. No defence was possible of the former attitude of the majority of Churchmen that these diseases were sent by God as a punishment for sin, and therefore ought to be left to run their course. The real question to be faced, if the clergy were to co-operate with the doctors whole-heartedly on this matter, was the attitude to be taken towards prostitution. Was prostitution to be considered a necessary fact in civilization? All those present would agree with him that if that institution, said to be the oldest in the world, could be suspended for five or ten years, these diseases would be brought within manageable compass, and probably within a single generation would be wiped out. Prostitution was not only antichristian but antidemocratic, cruel, degrading, and indefensible, and however impossible it might seem at present to wage war against it successfully, such warfare was a thing they must never give up. Plato, speaking of the unnatural vice which was common in the Greece of his time, said that its abolition, however desirable, was a castle in the air; yet, owing to various causes, of which Christianity was one, that particular vice had been driven underground, and had become enormously less common than in pagan times. Plato also spoke in a very fine way on the general question of continence, reminding his readers that a great many athletes maintained perfect continence during their training, and if these men exercised this self-restraint for a corruptible crown, how much more should they all for an incorruptible. The clergy wanted to be assured that doctors were doing all they could to discourage young men from promiscuous intercourse. He had been reading a German book on population—he did not think the author was a religious man—which declared that every doctor ought to warn his patients that there was only one certain way of escaping these diseases, and that was by avoiding promiscuous intercourse altogether.

#### *The Preaching of Continence.*

Much more knowledge was needed on the whole question of continence. The strangest views were propounded, as, for example, that continence was impossible—a view very freely held on the Continent, even by physicians. He had not himself heard many confessions, but, so far as his observation had extended, human nature presented enormous differences in this respect, and there were a very large number of people who not only remained chaste during boyhood and youth, but were never very seriously tempted to be otherwise. When he was at Eton he believed the very large majority of the boys lived cleanly, and he was very decidedly of that opinion with regard to his friends and companions at Cambridge. On the other hand, there were some who held that continence was easy and harmless for all. The facts, so far as he knew them, were that there were a very large number of people who would be much healthier and happier married than single, but that probably in no case did any serious physical consequences result from the pure single life. That, he thought, was what most doctors would say so far as men were concerned; whether they would say the same about women was more doubtful. Vital statistics were sometimes appealed to to show that celibacy shortened life; but these statistics were vitiated by the fact that a good many unmarried people shortened their lives, not by continence, but by promiscuous intercourse, and by the fact that the reason why many people did not marry was ill health or general weakness. On the

other hand, there were the unusually long lives of many celibate priests.

Many years ago he was asked to subscribe to a religious society for the encouragement of sexual purity. This society circulated a sermon by Dr. Pusey, which contained a very lurid but not altogether untrue description of venereal disease, and then went on to speak in even stronger terms of those solitary bad habits into which the schoolboy and the schoolgirl are prone to fall. Dr. Pusey said that his brain reeled when he thought of the punishments of God upon this sin—insanity, blindness, and so forth. He (the Dean) wrote back and said that he could not give the society any support so long as it circulated that sermon, because not only were the statements untrue and cruel, but they were almost certain in many cases to produce sexual hypochondria. Many would be familiar with a monograph by Sir James Paget showing the terrible mischief done by threats which had no scientific support at all. The society promised that the sermon should be withdrawn.

He next touched upon public school morality. Many people considered that a form of immorality which was sometimes found in public schools was utterly unnatural and monstrous. But it was desirable that it should be known that during the first two or three years after puberty the sexual impulse was quite undifferentiated, and there was nothing at all unnatural in boys falling in love with each other or in girls doing the same. Of course, those in charge of the schools must prevent such affections finding any impure outlet, but there was nothing innately shocking in such affections, and in normal cases, he imagined, the impulse died away before 21. One heard occasionally also of elderly men who had lived a more or less respectable life falling suddenly into this vice, perhaps bringing about their social ruin. In the majority of cases he believed this was purely a pathological thing, indicating not only the approaching extinction of the sexual powers, but in many cases a tumour of the brain or some other condition of oncoming insanity. It might be that very cruel injustice was done by condemning as utterly reprobate and abominable men who were not responsible for their actions. Here, again, there was need for enlightenment from medicine.

#### *Birth Control.*

Finally, the Dean spoke on birth control—a social, racial, and economic, as well as a moral and medical question. He reminded the audience of the facts with regard to the increase of population. The birth rate in this country reached its maximum of 36 per 1,000 in 1877, when the death rate was 21 or 22. The birth rate had declined, almost in a straight line, except for the war years, until last year the figure was 20 per 1,000. The death rate, thanks mainly to the skill of the medical profession, had declined in a parallel line, and last year was 12 per 1,000. Were there any in that room who would hold that the old birth rate of 36 per 1,000 could have been maintained, in view of overcrowding and unemployment, with a death rate of 12? It seemed to him quite obvious that in some way or other the birth rate had to decline, and also that a time must be reached—not very far ahead—when this country could no longer support a further increase in the number of its inhabitants. That being the case, it did not seem very creditable either to their profession or his own that they should have joined in discountenancing and condemning any attempts to regulate the birth rate, and he said this with the more confidence because the statistics showed that the very bottom place in the birth rate was held by the members of their two professions. That was not satisfactory, nor even honest. The differential birth rate, of course, was a very striking and dangerous symptom—the birth rate was two and a half times as high among unskilled labourers as among members of the learned professions. With regard to methods of controlling births, opinions differed both as to moral and medical aspects. He would plead only for candour and honesty.

His main object in that address had been to ask the medical profession to enlighten the public more than in the past. A great amount of ignorance, not confined to uneducated people, prevailed on all matters relating to sex. He wondered whether it was not possible for a handbook to be issued by an influential and authoritative body of doctors setting forth those facts which it was most useful for clergy and teachers and parents to know. This handbook should include some information on eugenics and the diseases which were strongly inheritable with a view to impressing it as a patriotic duty on those suffering from such diseases that they should abstain

from parentage. Doctors in these days had entered into the position of the priests of the Middle Ages. They heard confessions, they imposed penances, sometimes fantastic ones. They were listened to, and what they said was accepted as authoritative. The physical and moral welfare of the country was largely in their hands. Let them tell the public what it was good for the public to know, and especially the clergy, to save them from making all manner of disastrous mistakes.

#### Discussion.

The CHAIRMAN (Dr. F. W. Goodbody) said that much of the credit of bringing the question of venereal disease out into the open belonged to the British Medical Association. He recalled that a large proportion of the signatures to a letter on the subject which appeared in the general press in 1913 were obtained at the Brighton meeting of the Association.

Mr. McADAM ECCLES said that he had the privilege of being present on most of the occasions when the committee of which the Dean had spoken was sitting at Westminster to consider the question of spiritual healing, and he recalled what a great amount of illumination both the clergy and the medical members received. As an outcome of the deliberations, the idea in his own mind was fixed that there were certain conditions upon which no amount of faith or any other form of mental healing would have any effect. He did not agree with the Dean, however, in putting a fractured leg out of account, because the patient who was suffering agony from a fracture could be helped by a process of mental solace combined with a slight physical action in the shape of massage. This produced no direct effect upon the fractured ends, but it put the patient into such a condition that nature could come in and help to unite the fracture. With a congenital deformity, however, he did not believe that any type of spiritual or mental healing would have the slightest effect. Mr. McAdam Eccles also made some remarks on the question of public school morality.

Dr. CRICHTON MILLER thought that the Dean's argument on birth control left a fallacy which was continually creeping into this question. If it were correct from the eugenic point of view that racially they should propagate less, it was no less necessary, but even more necessary, that the next generation should come from the above-par and not from the below-par portion of the population. Whether the indications of eugenics were that the birth rate should go up or come down, the above-par section of the population should be fully represented in the birth rate.

Mr. BISHOP HARMAN said that he was not afraid that the people of this country would degenerate because the professional classes did not breed at the same rate as the hardy labourer. If the pedigrees of any well born family were traced it would be found again and again that the family had been rejuvenated by stocks from very lowly ranks, and it was clear that often genius had come by way of this lowlier introduction. Referring to what the Dean had said about Dr. Pusey's sermon, Mr. Harman expressed the opinion that a great deal of harm was done by certain lurid pamphlets which depicted in overdrawn terms to frightened youths the consequences of a habit into which they had fallen, not always as the result of bad example or natural depravity, but more or less innocently. He could not understand the attitude of mind of those who cried out against a legitimate measure of birth control and the spacing out of the family, and when people who themselves were celibate cried out against it the position became absurd. Birth control began with the postponement of marriage; from plain physiological facts it was evident that the later the marriage the less would be the procreation. He did not believe that the professional classes practised birth control so much by deliberately reducing their families after marriage as they did by postponing marriage to such an age that the resulting families could not be large. He saw nothing immoral in a properly regulated practice of spacing births. In conclusion, he thought it something to be proud of that in a great city like London there was so much happiness and well-being, so much mutual forbearance and good humour, and so much comeliness of person and dwelling.

Dr. C. F. HARFORD believed that psychotherapy was only just at its beginning. While not himself a Freudian, he thought that the revelation which had come through Freud ought to be recognized, and when it was considered how extraordinarily the sexual problem came into prominence, some care ought to be exercised in criticizing Freud. The best results would be secured in dealing with the abuses of the day from mental hygiene.

A VISITOR whose name was not given declared himself to be the fourteenth child of his parents, and he himself urged the advantages of large families. It was the solitary child, not the child in a large family, who became addicted to self-abuse. If England practised birth control she would lose her empire.

Dean INGE, in reply to a warmly accorded vote of thanks, said that still more discussion between the two professions was desirable. He had been laying stress on what was, perhaps, the more important side of such discussion—namely, the advantage the clergy would derive from more instruction from the medical profession. But he knew that many medical men in their practice realized the importance of religious belief in curing the sick body as well as the sick mind. Nothing was more untrue than the French proverb that where there were three doctors there were two atheists. He had found in his own experience of the profession a deep spiritual sense and the feeling of a priestly vocation. Some of the most famous physicians owed a great deal of their success to their power, not only of reading character, but of acting upon character, and very often by purely religious or spiritual methods. The new psychology had thrown a great deal of new light on the nature of temptation and the best way of resisting it, and it was to be hoped that before very long this new knowledge might be co-ordinated and systematized, and put into a form available for responsible teachers.

## England and Wales.

### PRESENTATION TO SIR DAVID DRUMMOND.

THAT it was a happy thought and a gracious act on the part of his colleagues to entertain Sir David Drummond to dinner on the occasion of his knighthood, and to present him with a piece of silver, was proved by the large number of friends who gathered in the King's Hall of the Armstrong College, Newcastle-on-Tyne, on February 28th. The dinner was, practically speaking, confined to the teaching staffs of the College of Medicine, the Royal Victoria Infirmary, the Maternity, Fever, and Dental Hospitals, and representatives from Armstrong College. Between eighty and ninety ladies and gentlemen were present. Dr. Cecil A. Cochran, chairman of council of Armstrong College and honorary treasurer of the University of Durham College of Medicine, presided. After the loyal toast had been honoured, the chairman proposed the health of "Our Guest." In a well arranged and thoughtful speech, masterly in detail yet in no wise savouring of redundancy, Dr. Cochran briefly reviewed circumstances in the life and professional career of Sir David Drummond which had led to his being recognized as worthy of the honour which had been conferred. In the College of Medicine he had held the chairs of therapeutics, physiology, and pathology, and finally of medicine; on the death of Sir George Hare Philipson he was appointed president of the college, a position which he had filled with dignity and to the benefit of all concerned. To the Royal Victoria Infirmary he had given many years of useful service, and by the patients his visits had been much appreciated. Two years ago Sir David was appointed vice-chancellor of the University of Durham. It was a timely appointment, for his year of office coincided with the visit to Newcastle-upon-Tyne of the British Medical Association, of which he had been elected president, one of the highest honours of the medical profession. All knew how well he discharged the duties of that office. Sir David Drummond's kindly manner and urbanity contributed considerably to the success of that meeting. Of their guest's professional abilities he would in such a gathering say nothing other than that several years ago he had been through his hands, and could therefore add his own testimony of appreciation to that of others of his patients. It was his pleasure not only to wish Sir David and Lady Drummond all the good things possible which an extended life might bring to them and to their family, but to ask their guest to receive, in the name of the members of the College of Medicine, the staffs of the Royal Victoria Infirmary, the Maternity and Fever Hospitals, a loving cup bearing the London hall-mark 1765, as a souvenir of the occasion, and to express the hope that it would be treasured by himself and by his family.

Sir David Drummond was not less happy in his reply than the chairman in his speech. There came, he said, occasions in the life of most men when they were embarrassed and

overcome by the kindness of their friends. Such was his position at the moment. In no words could he adequately express his feelings. He was much touched by the many indications of friendliness which the conferment of the honour had elicited, as revealed in the several hundreds of letters he had received. Many of these alluded to the honour having been long delayed. To that circumstance he himself took no exception. Others alluded to his youthful appearance and asked him for the secret. He had no secrets that he would give, other than that in having his two sons living with him he was constantly in touch with modern opinions and with the changing thought of the times. Nor was he above playing with his grandchildren. From these and other sources he drew the influences which kept him young. There were several things which had contributed to such success as he had achieved. Shortly after he came to Newcastle a vacancy occurred on the staff of the infirmary, and he obtained the appointment, and for over thirty years, as they had been told, he was an active member of the staff. Other appointments gradually came his way, for opportunity had befriended him. On one occasion he asked a well known predecessor in office in the College of Medicine as to how success and honour had come to him, and the friend replied that it was by always having the best of everything and by compliance with conformity. There was much in this attitude to men and things which was true and worthy of copy. So far as his own professional career was concerned he had always attached great importance, as Professor Stuart McDonald knew, to frequent visits to the *post-mortem* room in the infirmary. Correlating the present with the past and looking to the future he too could only express the hope that there was still some useful work left for him to do. To him at any rate there were solace and comfort in the words:

"Grow old along with me,  
The best is yet to be,  
The last of life for which the first was made."

Sir Theodore Morison, Principal of Armstrong College, proposed a vote of thanks to the chairman, who in responding thanked those who had so successfully contributed by voice and instrument to the harmony of the evening.

#### POST-GRADUATE WORK OF THE UNIVERSITY OF BRISTOL.

Arrangements have been made for a series of post-graduate demonstrations to be given in the medical theatre of the University of Bristol during April and May. The demonstrations will be given at 3.30 on Thursdays, beginning on April 12th, and will be followed by discussions. The demonstrations of the present course will deal with nasal catarrh, conjunctivitis, painful feet, endocrinology, cardio-vascular disease, the treatment of stricture and prostatic enlargement, hysteria, and normal and acquired resistance to disease. The fee for the course is one guinea. Further particulars can be obtained from the Director, Post-Graduate Medical Studies, Pathological Department, University of Bristol, who will also supply information with regard to the subjects which will be available for the selection of courses of study at local centres during 1923.

#### NEW AMBULANCE STATIONS IN LONDON.

The London County Council proposes to establish three new ambulance stations—at Highbury, Paddington Green, and Capham Junction. When the service was established in 1915 six stations were provided, and a definite area allotted to each. For a few years the stations were able to deal with the calls within their respective areas, but as the efficiency of the service became known calls from other districts became increasingly frequent, leading, on occasion, to two or even three ambulances being absent from their own districts. During a recent period of eight months the average time taken to reach each case dealt with by the service was 8.7 minutes from the receipt of the call at headquarters, but in certain boroughs, more particularly those to be served by the new stations, the average time was 10, 11, or even 12 minutes. The cost of the new stations, in buildings, ambulances, and equipment, will be £7,650, and in annual maintenance about £6,300. As an experiment in economy, at one outlying station only one attendant instead of the usual two (in addition to the driver) is to accompany the ambulance in response to calls.

## Scotland.

#### REPORT OF THE ROYAL EDINBURGH ASYLUM.

THE 110th annual report of the Royal Asylum at Morningside, Edinburgh, which appeared last week, affords as usual much interesting information. The patients treated during the year number 1,536, of whom 123 were discharged recovered, 221 were discharged unrecovered, and 167 died. An appeal is made for subscriptions to help relatives who are endeavouring to pay for the maintenance and treatment of patients, so as to prevent their falling into the category of pauper lunatics. It is pointed out that the current cost for a patient in this asylum is between £60 and £70, and that if the charitable support of mental hospitals were as great as that of hospitals for bodily diseases the managers would be enabled to make grants to the friends of patients for this purpose. The managers have in contemplation the erection of an out-patient department to the east of the entrance to the asylum. It is intended that this should be available both for purposes of consultation, like the out-patient department of an ordinary hospital, and also, since beds would be available in the clinic, for the reception of patients for short periods of treatment without the necessity of any legal formalities. Four nursing homes for nervous or mild mental disorders already exist in Edinburgh, and here early cases can be treated by the family physician without the patient being certified or sent to an asylum. This practice is legal in Scotland although not in England, and these homes have received much attention from visitors from England, the Dominions, and America. With regard to the practice of psycho-analysis, it is admitted that no dramatic recoveries are to be expected by such means in the vast majority of cases of definite mental disorder. Nevertheless the employment of psychotherapy gives to the attendant an understanding of the patient's symptoms and mentality which is of the utmost value in general treatment and management. The substantial decrease of the annual deaths from general paralysis in England and Wales during the three years 1919-21 amounts to 28 per cent. in the case of men and 41 per cent. in the case of women, but is not so noticeable in Scotland, where the reductions amount to 12 per cent. for males and 6 per cent. for females, as compared with the average of the previous twelve years. The explanation offered is that the severe influenza epidemic of 1918 may have exerted a protective influence such as malaria is alleged to afford, or that the recent lessened consumption of alcohol may be the effective factor.

#### RECTORIAL ADDRESS IN EDINBURGH.

The Right Hon. D. Lloyd George last week delivered his address as Lord Rector to the students of Edinburgh University, taking as his subject "The qualities of a politician." On this occasion the reception accorded to the Lord Rector was even more boisterous than usual. Paper streamers hanging from the sounding wires, coloured balloons filled with buoyant gas, and a gigantic look suspended over and in front of the speaker decorated the McEwan Hall, in which the address was delivered. Mr. Lloyd George had in which the address was delivered. Mr. Lloyd George had a fairly good hearing, though there were constant impromptu interruptions, to which he retorted with a readiness that won the enthusiastic applause of his student audience. He regarded courage as the first requisite of the politician who desired success, and next after it he placed a training in clear effective speech. At the luncheon in the Students' Union which followed the address Mr. Lloyd George referred to the fact that seven of his colleagues in the late Government had been graduates of the University of Edinburgh. The occasion ended with the usual torchlight procession in the evening, which was remarkable in the history of these carnivals for the great number of women students who took part.

#### DECLINE OF TUBERCULOSIS.

The Committee of Management of the Royal Victoria Hospital Tuberculosis Trust in its eighth annual report submitted statistics showing that the mortality from tuberculosis had fallen during the twenty-five years 1890-1915 by 30.9 per cent. in England and by 42.4 per cent. in Scotland. Tuberculosis had not been increased by the war, and in 1920 a further drop had taken place, which was maintained in 1921. During the past year this Trust had opened the Southfield Sanatorium Colony, which it was hoped would soon be expanded to one hundred beds.

## ROYAL (DICK) VETERINARY COLLEGE CENTENARY.

At a recent meeting of the governors of the Royal (Dick) Veterinary College it was intimated that the Secretary for Scotland, through the Board of Agriculture, had agreed to discharge obligations of the College, and to provide an annual sum to meet the financial deficit in future between income and expenditure. This promise of help is satisfactory since the College, in addition to training veterinary students, does a large amount of valuable research work and forms an important adjunct of the University in regard to the diplomas of B.Sc. and D.Sc. in Veterinary Science. The College celebrates this year the hundredth anniversary of its foundation, as it was in November, 1823, that William Dick, the founder, delivered his first lecture. Originally little more than a lecture room and a shoeing forge, repeated additions were made until the school was rebuilt, first in 1886, in Clyde Street, and again, on its present site at Summerhall, in 1916. Valuable scientific and educational work has been done in the past century by the college, and its old students are scattered all over the world. As a permanent memorial of the centenary it is proposed to found a post-graduate research fellowship, on such a basis that the holder may be able to study the cause and prevention of animal disease, not only in this country, but also in institutions abroad. For the purpose of the endowment of this fellowship a bazaar is to be held in Edinburgh at the end of November; this, on account of the close relation of modern veterinary science to preventive medicine, will, we do not doubt, have the support of the medical profession.

## Ireland.

## SUPERANNUATION OF DISPENSARY DOCTORS AND DISPENSARY MIDWIVES.

At a recent meeting of the Dail (Irish Free State Parliament) Sir James Craig, M.D. (Dublin University), moved the following amendment to the Local Government (Temporary Provisions Bill):—To add to Subsection (5) the following:

"A dispensary doctor or a dispensary midwife, who has become incapable of discharging the duties of his or her office with efficiency, by reason of a permanent infirmity of mind or body, and who has served as an officer of a local authority for not less than twenty years, may, with the permission of the Minister, be allowed to resign his or her office, and he or she shall be entitled to receive from the local authority an allowance not exceeding two-thirds of the salary, fees, and emoluments which he or she was in receipt of at the time of his or her resignation."

Sir James Craig said that he was aware that the amendment might be ruled out of order because it suggested something of a permanent character in dealing with a temporary bill. There was, however, a strong case for the amendment. If we know that dispensary medical officers, and midwives also, remained in office long after they were capable of performing their duties, because the pension to which they would be entitled was so small that they would not be able to live on it. That dispensary medical officers or midwives should remain in office when by reason of infirmity of mind or body they were unable to perform their duties properly was unfair to them and a most serious matter for the poor of the district. Sir James Craig quoted the case of a dispensary doctor in Connaught who had to cover fourteen square Irish miles, and continued as follows:

He is getting £220 a year as dispensary medical officer. He is getting £15 a year as medical officer of health. Ye Gods! think of £15 a year—£101 a day for looking after the public health in an area covering fourteen Irish miles. He tells me also that under no circumstances could he possibly make more than £50 a year in private practice. He has possibly to keep a motor and possibly comparison (I think justly) with his neighbourhood, who receives six hours a day. The doctor is liable to be called out at all hours of the day and night to cover this huge district, and he has to go into houses where typhus fever is frequently rampant. The point I make is that an attempt should be made to encourage people of good education to go to those districts, and unless they are going to get a decent salary and pension when no longer fit to perform their duties I do not think that such men would go there.

Mr. Lyons (Labour) in supporting the amendment, said that some country doctors were certainly very badly hit. It had been the custom to include emoluments and bonuses when calculating superannuation; the bonuses would only count since the war, but were any proposal made to do away with it he would wish to see the amount added to the salary. It was essential to give a professional man a living wage, and he heartily agreed with Sir James Craig that steps

should be taken to encourage the best men to go to the country districts. For this they must be suitably paid and no member of a local council should try to repudiate standing orders to the effect that doctors shall receive superannuation up to two-thirds of their salaries. He approved Sir James Craig's amendment that midwives and dispensary doctors in feeble or delicate health should be allowed to resign and receive two-thirds of their salaries.

Mr. Ernest Blythe (Minister of Local Government) said that the bill, if carried, would only run for twelve months, and it was not right to propose any change not required by an immediate emergency or to correct some confusion that had arisen. He understood that the fixed rule was that a medical officer of twenty years' service, on retiring on account of infirmity or any other cause, was entitled to receive two-thirds of his salary as a pension; this had the appearance, at least, of undue generosity. He knew cases where doctors, like other people, had got medical certificates to the effect that they were unfit for work, who afterwards proved not to be so ill as supposed. At present a dispensary medical officer was entitled to a pension if with ten years' service; if with less than ten years he was entitled to a gratuity. The pension could not be less than one-third of the salary, and if the doctor appealed it was possible for the Department in its discretion to increase the pension up to two-thirds. If a doctor retired on account of ill health after twenty years his position, which before the Act of 1919 was perhaps somewhat unsatisfactory, was now reasonably satisfactory; he could not accept the amendment.

Sir James Craig said he did not wish to press the amendment if the Minister would not accept it; if the principle were accepted he would be satisfied.

Professor W. Magennis (National University) appealed to Sir James Craig to stand his ground and to obtain recognition of the principle. A pension was deferred pay, and he appealed to every democratic member to remember that one of the fundamental principles of democracy was that the labourer is worthy of his hire. The amendment was designed to encourage medical practitioners with high qualifications to enter the service; he hoped that Sir James Craig, if the principle were accepted, would ask as a corollary that the amount given by the Act of 1919 should be increased. In reply to the argument that a permanent change should not be made in a temporary bill, Professor Magennis contended that the Minister had himself strongly defended a clause which would alter permanently the financial resources of the people it affected. He called on the Dail to place on record that it did not approve of the niggardly treatment of the medical servants of the public, particularly in the poor districts.

Mr. Blythe, in reply, promised that a permanent Act should at once be prepared and that every consideration would be given to the proposal of Sir James Craig, who thereupon withdrew his amendment.

## Correspondence.

## DR. HALDANE'S CONCEPTIONS OF BIOLOGY.

SIR,—The attention of all your readers must have been arrested by the masterly and impressive Lecture of Dr. Haldane in your columns of March 3rd. The law of reciprocal reaction could not have been set forth and illustrated in a more telling way. May one of your readers, unversed in philosophy, venture, for others' sakes perhaps as well as for his own, to ask one or two questions of the accomplished writer? Dr. Haldane makes much use of the words "mechanism" and "mechanistic"; he uses also the words "machine" and "mechanical." If there be a difference may we have it defined? If there be none, we artless persons would find "machine" (or machinery) and "mechanical" more familiar, more lucid. If "mechanistic" be more abstract is it not the more vague? Now by a machine do not we mean some tool—say a chisel or a locomotive engine—which is but an extension and fortification of the human hand or limb? Apart from man's hand it has no energy, no life; it cannot direct itself, it cannot grow or feed itself, it cannot repair itself. If this be so, how can a living creature be called in any sense, or in any philosophy, mechanical? Yet Dr. Haldane speaks of "the mechanism of kidney secretion" (p. 362). It is true he says that such it cannot be, but does he not use a great deal of protestation about it! Nay, may he not be deceiving himself if he concedes something more to the word than he would attribute, say, to a hammer or a spade? May he not be tending to use the word "mechanical" to mean an inviolable order of events? If so does he resent or discredit this inviolable order?

One more question: Dr. Haldane's conception of the peculiar qualities of life in action is as large and vivid as it is intimate; but where are we to begin? Where do we take off? If life is a circle, not vicious but virtuous, how and where does the circle establish itself? In other words, where are the marches, if any there be, between life and not life? For example, Dr. Haldane—who of course cannot in one

lecture deal with every side of his vast subject—says little of biophysics, and, I think, nothing of the properties of colloids? But is he of opinion that there are no features in these activities, inward and outward, of molecular groups or of colloids that verge or even trespass upon those of life?

Before I close, may I reflect upon the word "environment," as ugly and ineffectual? Dr. Haldane probably feels this defect, as we all have felt it. In certain of his sentences, especially in such sentences as the "internal environment of a cell" the phrase hardly speaks for itself; it does not tell. Cannot some other and better word be found?—I am, etc.,

Cambridge, March 6th.

C. A.

#### FUNCTION OF THE ADRENAL GLANDS AND ITS RELATION TO CONCENTRATION OF HYDROGEN IONS.

SIR,—Further work has led me to modify the final conclusion of my paper on the above subject—an abstract of which appeared in the *BRITISH MEDICAL JOURNAL* of January 20th. In the full paper, appearing in the April number of the *Indian Journal of Medical Research*, this conclusion will read as follows:

"While the attempted exercise of an emergency function by the adrenal glands may be expected to occur in conditions of grave acidosis the effect of lesser degrees of acidosis will be to enhance the action of such amounts of epinephrin as are normally discharged by the adrenal glands."

—I am, etc.,

Coonoor, India, February 13th.

R. MCCARRISON.

#### THE ORIGIN OF PITUITARY SECRETIONS.

SIR,—It is generally admitted that the terminology of the pituitary and of the extracts prepared from the gland is regrettably confused. The lack of uniformity is partly due to the fact that pharmacological investigation into the effect of pituitary extracts has not been brought into satisfactory relation with the histological differentiation of this organ. The following suggestion, which emerges from work on amphibia, may indicate a line of inquiry which can perhaps throw light on the question in its medical bearing.

On the medical side, at least two categories of response are of interest in connexion with the action of "posterior lobe" extracts: the pressor effect and the more general influence exercised upon plain muscle, such as that of the uterus. The recent work of Dale, and of Dudley and Dale, provides very strong confirmation for the view, due originally to Schafer, that these responses are evoked by distinct autacoids, the "pressor" and "oxytoxic" substances. The pars intermedia, hitherto regarded as the sole glandular portion of the posterior lobe, has generally been recognized as the source of these secretions, which are supposed to diffuse into the pars nervosa. This interpretation is not without difficulty. Herring (1914) showed that whereas extracts of the pars intermedia of the mammalian pituitary have an oxytoxic activity little less than that of the pars nervosa, the pressor effect is almost exclusively restricted to extracts of the latter. Since the work of Herring new light on the comparative physiology of the pituitary has been shed by the researches of Tilney and Atwell, who have shown conclusively that there are three epithelial constituents of the gland—the pars anterior, pars intermedia, and pars tuberalis. In mammals the pars tuberalis lies dorsal to and sometimes in contact with the pars intermedia, being applied closely to the floor of the brain, so that anatomically the two are not distinguishable except in certain cytological peculiarities and by their totally different derivation in the embryo. In many lower vertebrates, on the other hand, especially in frogs and toads, the three lobes are both histologically distinct and anatomically discontinuous, the pars tuberalis forming two separate glandular plaques on the sides of the tuber cinereum. Judged from the pressor, "galactagogue," and pigmentary responses which they elicit posterior lobe secretions are physiologically equivalent in amphibia and mammals; and it has been conclusively shown by Allen (1920) and Swingle (1921) that the pars intermedia secretion and not that of the pars tuberalis is responsible for the pigmentary response which occurs in amphibia. Since the pigmentary response is almost certainly not elicited by the pressor, but probably by the oxytoxic or uterine stimulant (Hogben and Winton, 1922), it is not unnatural to suppose that the two posterior lobe secretions originate in the two distinct glandular components of the posterior lobe, the pressor secretion in the pars tuberalis and the oxytoxic substance in the pars intermedia. This would satisfactorily

explain Herring's observations, and if substantiated provide an agreeable basis for a more uniform nomenclature.

The suggestion is amenable to experimental test, since all the lobes of the gland can be readily separated for testing with the assistance of a binocular in the case of the common frog. It may, therefore, be of interest to those who are studying the pituitary from the pharmacological standpoint.—I am, etc.,

LANCELOT T. HOGREN,  
Lecturer in Experimental Zoology, University  
of Edinburgh.

February 22nd.

#### PRIMARY UNION AFTER OPERATION FOR APPENDICITIS.

SIR,—I was surprised to read in Mr. Riddell's paper on primary union after operation for suppurative appendicitis (*February 24th*, p. 322) that he had had unfavourable results by treating similar wound conditions with bipp.

In Mr. Willan's clinic in the Royal Victoria Infirmary, Newcastle, it has been the practice for some years to treat the cut abdominal wall by the bipp method in all cases of suppurative appendicitis. It should be stated that in most cases it has been customary to drain the abscess cavity for a few days as a precautionary measure.

Mr. Willan alone, in his war service and in his clinic here, has done considerably over eighty cases. The results have been uniformly good; suppuration in the abdominal wall wound, formerly an expected result, is now quite rare, thanks to bipp. Convalescence is materially shortened, important alike for patient and for the earlier freeing of a much needed public hospital bed. Further, post-operative hernia following suppurating appendicitis is now seldom seen. The bipp should be applied to the cut abdominal wall before the peritoneal cavity is opened, both to the subcutaneous tissues and the muscles; but it should be emphasized that success by this method can be assured only if the surgeon faithfully adheres to the details laid down by Professor Rutherford Morison; these details can be obtained on referring to his book on *Bipp Treatment of War Wounds*, published by the Oxford Press.—I am, etc.,

JOHN BRUMWELL,  
Hon. Surgical Registrar.

Newcastle-on-Tyne, March 2nd.

#### HOSPITAL POLICY.

SIR,—"I told you so" is usually the most irritating and ungracious reminder of past errors that had better be forgotten. But there are occasions when it is legitimate to remind ourselves and others that what we foretold has come to pass, and to suggest that such an experience of successful judgement is a good augury for a continuance of correctness of judgement in related subjects.

The first or interim report of the Voluntary Hospitals Commission provides a useful text on which to base a claim for correctness of judgement by the British Medical Association on the trend of hospital affairs. The Association gave evidence before the Cave Committee and put forward, amongst several propositions, (1) a definition of what is the characteristic feature of voluntary hospitals, and (2) a proposition as to how a Government subsidy could be given to such hospitals without jeopardizing the essential feature of such hospitals.

1. The Association stated that the feature of a voluntary hospital which was worthy of maintenance in all interests was its voluntary method of administration; and later this was put into shape as a clear definition, which is now the policy of the Association:

"The Association maintains that the essence of the voluntary hospital system is the independent and voluntary management, and that this is not necessarily related to the conditions of service of the medical staffs."

This, the first attempt at such a definition, was severely criticized by many, and with not a little attempt at ridicule that the Association should be so impudent as to attempt to propound a new definition of so old a word as "voluntary." Wisdom is justified of her children. For the Voluntary Hospitals Commission has arrived at a definition which is as nearly the same as two tongues can voice it. In par. 3 of their report the Commission say their first task was to determine what was a voluntary hospital, and state:

"We were clearly of opinion that voluntary management by a responsible committee was an essential condition."

Their readers are left in no doubt as to what they mean by "voluntary management"; it is shown on page 13 to be the antithesis of "Government and municipal control."

The supporters of "voluntary contributions" as the feature of voluntary hospitals may derive some small comfort from the fact that in deciding to which of the many voluntary hospitals the Commission should disburse their grants they limited their interest to those hospitals which are "wholly or mainly supported from voluntary sources" or endowments. Since these emergency grants were necessitated by abnormal conditions, it may be supposed that those voluntary hospitals which derived their funds mainly from patients paid for by various authorities would need no emergency grant, for they could vary their charges with the variations of money value.

It is noteworthy that in defining a voluntary hospital the Commission made no reference to the medical staff. This is an interesting negative commentary by the successors of the Cave Committee, which in its report published the *obiter dictum* of two (unnamed) witnesses who claimed that the "bottom" of the voluntary system was an unpaid medical staff, for did not these "two distinguished physicians" state that with a paid staff "the bottom would drop out of the voluntary system"? Apparently the Commission agreed with the Association, and did not find that the terms of service of the medical staff had any necessary relation to the voluntary hospital system, neither as bottom, top, sides, handles, nor even as a decorative feature.

2. The Association, in giving evidence before the Cave Committee, stated that in its opinion there was only one way in which the Government could subsidize the voluntary hospitals without jeopardizing that independence which was their characteristic feature. This was by handing over in bulk such sum as it proposed to disburse to some intermediary body which would allocate the funds as it deemed most fitting, and the Association cited as a precedent for this mode of action the University Grants Committee. That proposition was accepted by the Cave Committee—it became one of its recommendations to the Government, and was accepted and acted upon by the Government. The report of the Voluntary Hospitals Commission shows that this policy has worked well; early suspicions on the part of some boards of management of voluntary hospitals have been allayed by the evident good faith of the Commission and its local committees; they find that the work of these committees does not threaten their proper independence.

The Association made a great break with old and cherished traditions when it recognized that the voluntary hospitals had duties to perform other than those of charities for the treatment of the very poor. This is set out in the statement of policy, thus:

"The Association recognizes a dual policy as regards the voluntary hospitals: (a) that the purely charitable side should be continued wherein the whole cost of the maintenance of indigent patients is met by the gratuitous contributions received by the hospital and on whose behalf the services of the honorary medical staffs are given gratuitously; (b) that other patients who are not indigent may be received for treatment at voluntary hospitals when they cannot pay for or cannot obtain adequate treatment elsewhere and that for them payment should be received by the hospital either from the patients themselves or on their behalf from the authority or body referring them to the hospital, and that on account of their treatment some method of remuneration of the honorary medical staff should be arranged."

Strong confirmation of this judgement of the Association is to be found in the report of the Somerset Voluntary Hospitals Committee, which is the first of these local committee reports to hand. The report reads:

"In a country where hospitals come into existence haphazard ... it is inevitable that the hospitals' position generally should disclose many defects, the most important of which seems to be the following [nine points are cited—of these I quote two]:

(a) The lack of ... patients of moderate means.  
(b) A too low ... tradition that hospitals are charitable institutions, poor, and the failure to give active recognition to the fact that the population wants a much better hospital service, open to all classes, and is willing to pay for it."

The satisfaction of a demand such as this will make the position of the medical staffs of the hospitals totally different from that which they willingly assumed in the old days when the hospitals were pure charities, and the policy of the Association requires the recognition of this change.

Again, the Association policy has given a clear lead in the matter of contributory schemes. Its standards of what should be found in such schemes deserve the close study of those interested in hospitals. And I learn that the more they are considered by hospital financiers the more they are found to give correct indications of policy. The report of the Voluntary Hospitals Commission states:

"Considerable progress has been made in organizing schemes of mass contribution, and this method of securing additional income has the hearty support of the Commission and the local committees. But very little definite information is yet available, and the Commission have issued a questionnaire to all local voluntary hospital committees asking for particulars of the methods adopted in their respective areas for the collection of income."

These schemes may prove of the greatest value in establishing the voluntary hospitals on a sure basis, or they may be destructive; which of these results is to come about will depend largely on the action of the medical staffs. If the staffs clearly insist that from the beginning these schemes are to be run in the best interests of the patients, the public, and of medical practice, then they will be genuinely self-supporting schemes by which both hospitals and patients will benefit; if they are regarded as merely devices to catch money without regard to sound principles they will bring discredit upon hospitals, engender irritation amongst the contributors, and breed suspicion between hospital boards and staffs, with resulting failure and possibly disaster to the voluntary system. There is urgent need in these matters for close co-operation between lay boards and medical staffs. Too often a board is so absorbed in making ends meet as to become greedy of money no matter how it comes, or how it may affect the medical staff, the mainstay of the hospital. So also with the local voluntary hospitals committees, there is need for more effective medical representation. This is recognized by the Somerset Committee, which suggests:

"That the local committees should be so constituted as to give to hospitals a fuller representation and to include a stronger expert element."

The moral of this letter in the "I told you so" form is to suggest that the Association, which has so well foreseen the problems which have confronted the new Commission and its local committees, is likely to be correct in its other anticipations, which indeed are based upon those which have already been tested and found to be true. I would therefore appeal with some confidence that those points of the Association policy which are as yet awaiting confirmation may be regarded as the necessary corollary of the changes in being, and that there should be given to the proposals of the Council for the next Representative Meeting a united support. I recognize the point of view of those who cling to old ideals, but I would suggest to them that in clinging too closely to the past they may endanger the future. The fascinating swaddling clothes of infancy are a trammel and a danger to lusty youth. There are some—I have heard their public statements—who declare that they will cling to and labour for a hospital that is a charity pure and simple, but that if change is to come let it come by sweeping all into a State hospital system with a fully paid staff. Such extreme utterances show a lack of vision, which does not agree with the versatility of Englishmen, who are accustomed to evolve measures suitable to changed conditions, rather than to plunge into the turmoil and destruction of revolution. The voluntary hospitals should continue to be charities in so far as charity is needed, but we must be glad that the need of charity is diminishing, and that there is now the greater need for these hospitals to provide for those who can with proper pride and self-respect pay their way. I believe that when this is done the voluntary hospitals will make a greater appeal than ever to the benevolent, and be more likely to swing the State hospitals into their own orbit of efficiency rather than to be swallowed up in a uniform State system.—I am, etc.,

London, W.1, March 3rd.

N. BISHOP HARMAN.

SIR,—I would comment briefly on the letters of Dr. Fothergill and Dr. Fletcher in the issues of the JOURNAL for February 24th and March 3rd. The latter considers that the voluntary system is tottering to its fall. On the other hand, the Voluntary Hospitals Commission, with Lord Onslow as chairman, which has been most carefully studying this question for six months, has had every facility for its accurate investigation, and includes the Chairman of the Council of the British Medical Association, states in its interim report just published, that "the results of our investigation and experience during the period under review show conclusively that the voluntary system possesses strong vitality, and that its chances of permanent survival are increasingly hopeful." The Commission also produces evidence that Lord Cave's Committee, which nevertheless strongly affirmed their belief in the voluntary system, were quite unduly pessimistic in their estimate of the financial position of hospitals. It would be interesting to

learn on what information hidden from this special committee Dr. Fletcher bases his opinion.

With much contained in Dr. Fothergill's letters I find myself in agreement; but when he affirms that "The tariff of payments for 85 per cent." (of hospital patients) "should be such as to pay in full the whole cost to the hospital, including remuneration of the staff," I am amazed. Whence is this money to come, and what patients, save those few paid for by public bodies, and the small "private" class, can raise it directly or indirectly? The hospitals of Brighton, where he resides, are distinguished as the birthplace of a contributory scheme, largely advertised at one time both in the medical and lay press as about to introduce a financial millennium in the hospital world; yet a deficit of £15,000 at the Royal Sussex County Hospital has just been the subject of investigation by a special committee and of considerable comment in the local press. I can conceive nothing likely to militate more seriously against the success of appeals to the public to remedy by their charity this lamentable condition, which seems to be, in such serious dimensions, peculiar to Brighton among county hospitals; than the propagation of a notion that 85 per cent. of the patients are able, directly or indirectly, to pay their full cost and remunerate the staff as well. Who will subscribe if this be true?

In conclusion I would quote from Lord Onslow's Committee again: "Some 976 approved societies have agreed to devote a portion of their surpluses to payments in respect of the hospital treatment of their members, and schemes have been approved up to the next valuation results (five years)." These schemes will yield about £200,000 a year. Again: "Up to July only about £30,000 had been paid out, although a considerable sum of money had accrued. We think that the societies are genuinely anxious to facilitate the disbursement of the money to the hospitals." This statement from such authority will, I hope, finally dispose of that ridiculous boggy of "manipulation of funds," set up so prominently without a particle of evidence by the Council, which, like the grotesque suggestion of "token payments," seems to me to be patently but a last desperate effort by the Council and Hospitals Committee to save their face, in retreat from a position which surely they must now perceive was hopelessly untenable from the first. The Chairman of the Hospitals Committee has not, I believe, the support even of his own colleagues on his staff. Mr. Eccles assuredly lacks that of his. What the attitude of the London Hospital staff may be I know not, but if, which I doubt, they support Mr. Souttar, they must be almost unique among the teaching staffs of London, and in such case would not have the remotest chance with their chairman and lay board, in the extremely unlikely event of their approaching these laymen with their policy.—I am, etc.,

G. C. GARRATT.

Chichester, March 3rd.

#### NAVAL HYGIENE.

SIR,—I observe that the Admiralty have appointed a committee "to deal with the accommodation required and available on H.M. ships and the complements that can be borne with the best possible advantage," and I note the marked absence on such committee of a representative of the Naval Medical (Sanitary) Department. Surely it would be in the direct and best interests of the service if an authority on naval hygiene were to have a place on such a committee when important factors in their deliberations—for example, cubic air space and ventilation—have to be considered.—I am, etc.,

MEDICUS NAVALIS.

February 26th.

#### Obituary.

J. BEATTIE MCFARLAND, M.D., M.Ch.,  
Lincoln.

We regret to record the sudden death of Dr. Beattie McFarland of Lincoln, which occurred in the house of a patient on March 2nd. Dr. McFarland was born sixty-six years ago at Omagh, co. Tyrone, and received his medical education in Belfast; he graduated M.D. in 1881, and M.Ch. in 1883, of the Royal University of Ireland. After assistant-ships in Glasgow and Sheffield he went to Lincoln, where he built up a large general practice. For many years he held the post of medical officer to the Lincoln Workhouse and of one of the local union districts. During the whole of the war he was on the staff of the 4th Northern General Hospital, having attained the rank of major when he was demobilized.

Dr. McFarland had long been a pillar of the British Medical Association, of which he first became a member in 1885. He was the Representative of the Lincoln Division of the Midland Branch from 1910 to 1914, and from 1917 to 1922; he was vice-chairman of his Division in 1915, 1916, and 1919, and chairman in 1920. He was one of the best and most faithful of British Medical Association men, and his death is a great loss to the medical profession in Lincoln.

A colleague (G.J.R.L.) writes: Everybody liked Dr. Beattie McFarland—he was a friend to all. During the war his professional brethren naturally saw much of him and learned to appreciate his thorough-going earnestness and kindness of heart. He would do anything to help, and when things were at their busiest he was always cheerful and ready to take any duty that lay to his hand. For many years he was the Representative of the Lincoln Division in the Representative Body of the British Medical Association, and the Association had no more loyal adherent. Many times at meetings of the Division he would say, "The B.M.A. has decided so-and-so," or "The B.M.A. does not approve of this or that." He loved attending the Annual Meeting and greeting his old friends, and he always brought back something new in the way of ideas to his fellow members at home. He had been chairman of the Lincoln Panel Committee since the commencement, and took an intense interest in the working of the Insurance Acts. He was a pattern of what the "panel doctor" should be—always as kind, thoughtful and thorough over the case of the "panel patient" as over that of any of his more wealthy patients. The profession in Lincoln and indeed in the country is the poorer for his passing.

THE LATE DR. W. P. PURVIS.—We regret that in the obituary notice of the late Dr. William Prior Purvis (JOURNAL, March 3rd, 1923, p. 399) it was stated that he was born at Belize, British Honduras. Dr. Purvis, we are authoritatively informed, was born on March 18th, 1869, at Greenwich, the eldest child of Dr. J. P. Purvis of Greenwich, and grandson of Dr. Prior Purvis of Blackheath (who was amongst the first batch of M.D.'s of London University). Dr. W. P. Purvis was educated at Roan School, Greenwich, of which he was a distinguished pupil.

#### Universities and Colleges.

##### UNIVERSITY OF LONDON.

At a meeting held on February 21st the Senate appointed Mr. H. J. Waring, M.S., F.R.C.S., to be its representative at the celebration of the 800th anniversary of St. Bartholomew's Hospital, in June, 1923; and Mr. Waring and (in respect of University College) Professor H. R. Kenwood, C.M.G., M.B., to be its representatives at the 34th Congress of the Royal Sanitary Institute, to be held at Hull in July-August, 1923.

##### ROYAL COLLEGE OF PHYSICIANS OF LONDON.

THE following supplementary list of candidates for the College licence who have conformed to the bye-laws and regulations, and passed the required examinations, will be proposed to the College for the granting of licences to practise physic:

H. C. Beecle, W. C. M. Berridge, F. Bishara, W. G. Booth, C. H. Budge, H. G. R. Canning, de Saram, R. V. Facey, G. E. Fisher, S. L. Joan O. Geldard, R. M. Geldart, F. Guiver, P. G. Harvey, A. I. Hall, H. Jackson, A. L. P. Jeffery, H. V. M. Jones, J. W. Joutle, B. Joynton-Bechal, G. Kitionsky, M. A. Mackay-Ross, M. Markiles, R. G. Lingford, \*Barbara V. Lucas, J. A. Lautre, L. B. Nichol, R. G. Morrison, A. L. de W. Naudé, \*Elizabeth M. Nicholson-Smith, \*Judith E. M. Ormerod, E. Orsmond, A. R. V. Patel, M. K. V. G. Pillai, \*Mary F. R. Pitt, \*Ethel B. Poole, T. P. Rees, \*Emily V. Saunders-Jacobs, P. G. Sedgwick, I. I. A. Shabed, G. D. Summers, S. E. Tanner, R. W. Taylor, \*Blanchette Thomas, \*Kathleen Tresilian.

\* Under the Medical Act, 1875.

##### SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in:  
Surgery.—M. Hawke, L. D. A. Hussey, C. M. John, \*S. W. Turtle, A. Vasudev.  
Medicine.—K. C. Chock, S. E. Hymans de Tiel, C. S. Laurence, \*J. A. Marriott, O. F. W. Robinson, S. W. Turtle, A. Vasudev.  
Forensic Medicine.—K. C. Chock, S. E. Hymans de Tiel, J. A. Marriott, O. F. W. Robinson, A. Vasudev.  
Midwifery.—F. Bienaschewitsch, E. W. Hicks, J. A. H. Sykes.

\* Section II.

The diploma of the Society, entitling them to practise Medicine, Surgery, and Midwifery, has been granted to Messrs. J. A. Marriott and S. W. Turtle.

## Medico-Legal.

### BIRTH CONTROL LIBEL ACTION.

STOPEs v. SUTHERLAND AND ANOTHER.

AN action for damages for libel brought by Marie Charlotte Carmichael Stopes, wife of Humphrey Verdon Roe, against Halliday Gibson Sutherland and Harding and More, Ltd., was heard before the Lord Chief Justice and a special jury in the King's Bench Division, on February 21st, 22nd, 23rd, 27th, and 28th. Judgement was delivered on March 1st.

The plaintiff was described in the statement of claim as a doctor of science of the University of London, a Fellow of University College, and a doctor of philosophy of the University of Munich; president of the Society for Constructive Birth Control and Racial Progress, and one of the founders and controlling and responsible for the conduct of a charitable clinic for birth control at 61, Marlborough Road, Holloway, N.

Dr. Sutherland, a doctor of medicine and bachelor of surgery of the University of Edinburgh, wrote a book entitled *Birth Control: A Statement of Christian Doctrine against the Neo-Malthusians*, which was printed and published by Messrs. Harding and More towards the close of March, 1922. The passages complained of in this book (pp. 101-102) were as follows:

"Exposing the Poor to Experiment."

"Secondly, the ordinary decent instincts of the poor are against these practices, and indeed they have used them less than any other class. But, owing to their poverty, lack of learning, and helplessness, the poor are the natural victims of those who seek to make experiments on their fellows. In the midst of a London slum, a woman, who is a doctor of German philosophy (Munich), has opened a Birth Control Clinic, where working women are instructed in a method of contraception described by Professor Melfroy as 'the most harmful method of which I have had experience.' (Proceedings of the Medico-Legal Society, July 7th, 1921.)"

"It is truly amazing that this monstrous campaign of birth control should be tolerated by the Home Secretary. Charles Bradlaugh was condemned to jail for a less serious crime."

The plaintiff alleged that by these words the defendants meant and were understood to mean that she (Dr. Stopes) was taking advantage of the ignorance of the poor to subject them to experiments of a most harmful and dangerous nature; that she was guilty of disgraceful, illegal, and criminal practices for which she should be punished by a term of imprisonment; and that she was a person with whom no decent or respectable persons should associate. Plaintiff (the statement of claim continued) had been thereby greatly injured in her credit, character and reputation, and in the way of her position of controller and organizer of the said clinic, and had been brought into public scandal, hatred, and contempt.

Dr. Sutherland in his defence maintained that the words complained of by the plaintiff were incorrectly set out in her statement of claim, and that material parts of the passage were omitted. He denied that the words did or could bear the meaning alleged by the plaintiff; in their natural meaning (he said) these words were true in substance and in fact—fair and bona fide comment, made and published without malice, on matters of public interest. Particulars were filed in support of this plea of justification and of fair comment.

Mr. Patrick Hastings, K.C., Sir Hugh Fraser, and Mr. H. Metcalfe, instructed by Messrs. Braby and Waller, of Dacre House, Arundel Street, Strand, appeared for the plaintiff; Mr. Ernest Charles, K.C., Mr. H. V. Rabagliati, and Mr. Harold Murphy, instructed by Messrs. Chalmers and Co., 11, Abchurch Lane, Strand, appeared for Dr. Sutherland; Mr. T. Mathew, instructed by Messrs. Mathew and Weld of 1, Gray's Inn Square, appeared for Messrs. Harding and More, Ltd.

#### The Plaintiff's Case.

Mr. Hastings, opening the plaintiff's case, said that although the alleged libel was an attack on Dr. Stopes's character, it was also an attack on her life work. She had devoted a great deal of time to promoting the theory and practice of what was known as birth control. Dr. Sutherland's book, which contained the libel, was largely concerned with advocating the views of the Roman Catholic Church, of which Dr. Sutherland was an ardent supporter. If Dr. Sutherland saw fit to criticize the plaintiff's works nobody could complain; but she was entitled to complain when a man in his position went out of his way to say that what she had done amounted in effect to a criminal offence. His book was directed against any system of birth control; she objected to

his statement therein that her work was experimentation on poor people unable to protect themselves. She objected, too, to the words which suggested that she was a person probably of German origin who was foisting her opinions upon the poor. Counsel then reviewed his client's parentage, upbringing, and academic distinctions in this country; and touched on her unhappy first marriage, which was annulled at her suit, and the effect of that experience upon the direction of her scientific outlook. Of her works written for the furtherance of the propaganda of birth control the best known was perhaps *Married Love*. Her teaching was that the only chance of happiness for married people was to realize that marriage was intended to be a joy to both, and not a curse to either of them; they should have children at a time when these could be properly cared for. Large sums had been received from the sale of the book, but Dr. Stopes had a wealthy husband, and practically every penny had gone to support her clinic and the society of which she was president and various distinguished persons were vice-presidents. That book, remarked counsel, the defendants had described as an obscene and criminal publication.

The first witness for the plaintiff was Sir James Barr, M.D., consulting physician to the Liverpool Royal Infirmary. He said he was acquainted with the plaintiff's work and with the establishment of her clinic, and thought it was doing an enormous amount of good. Information which normally all wealthy people had at the present day should, he held, be given to the poor as well. So far as he understood them, the methods employed (the cap and the quinine pessary) were very effective and very safe. Sir James Barr added that he was not appearing in the capacity of a vice-president of the British Medical Association, because the Association had not expressed any opinion upon this matter; he was a vice-president of the Constructive Birth Control Society. In cross-examination he expressed the view that Dr. Stopes's *Married Love* and *Wise Parenthood* were more suited for the married than for the young, though he did not think it would be utterly demoralizing if these books, describing sexual acts and practices, came into the hands of young people. He agreed that the "gold pin" device, of which he had no experience, would be an abortifacient if inserted into the uterus of a pregnant woman. He did not agree that the occlusive or check pessary was a dangerous thing, even when adjusted by the patient herself. The essence of the clinic was teaching the use of the check pessary.

The plaintiff, Dr. Marie Stopes, giving evidence, referred to her academic career, scientific travels and researches, educational work, married life, and writings on birth control. She said that a total reduction in the birth rate formed no part of her campaign; she advocated a decrease of the birth rate at the wrong part and an increase at the right end of the social scale. The object of her society was to counteract the steady reduction of the birth rate among the thrifty and sound, and the reckless breeding among persons at the other end of the social scale. Her clinic was founded, as a part of the campaign and with her husband's assistance, in March, 1921, in order to reach in a helpful manner the overburdened working-class women who were ignorant of the knowledge contained in writings on the subject. Besides the midwife in charge there was a visiting doctor who saw patients at the clinic. There had been no experiments upon any persons, rich or poor.

In cross-examination by Mr. Charles, witness agreed that she was not a medical practitioner; she was a doctor of science. When Dr. Sutherland's book came out she wrote for a copy, and two or three weeks later her husband, as honorary secretary of the Birth Control Society, wrote inviting him to debate his views with them at the Essex Hall. Counsel read a review that appeared in the issue for May, 1922, of *Birth Control News*, the journal of Dr. Stopes's society:

"Dr. Sutherland's book will impose only on those who are more ignorant than he is. It is nicely calculated to encourage the biased in their prejudices, for now, when speaking against birth control, they can say 'A doctor says so!' They will probably forget he is a Roman Catholic doctor. The omissions from the book are quite as remarkable as its lies. We could fill our columns in illustration of this, but space is too valuable."

Witness agreed that individual doctors had, in a scattered way, said the same sort of thing as Dr. Sutherland before he wrote that book. There was correspondence in the *British Medical Journal* in which a certain number of opponents published letters. She agreed also that very much worse things than the alleged libel had been said of her as a private individual by the "gutter press," in which term she included the *New Witness*. She knew there was a strong feeling both for and against contraception. Her book, *Wise Parenthood*, was described by her as "a practical sequel to *Married Love*." In the ninth edition she omitted a paragraph addressed to the "more careful women" on the "aesthetic" value of the gold pin (or wish-bone) pessary, which appeared in the seventh edition, because she found that English doctors were not so familiar with contraceptive technique as American doctors. Later she said: "I have since writing my books been approached by hundreds of medical practitioners,

giving me advice, offering me knowledge; many, many of them offering me a share in business concerns if I would take up and advertise various instruments." She added that she had no personal experience of this gold pin. The method she especially recommended was the small occlusive pessary for the cervix, invented in 1881 by a medical man—the cervical cap which adhered by natural suction. To have had some sort of declaration attached to her books, to be signed by the purchaser, would in her opinion have been an incitement to prudence. Witness was next taken over a passage in *Married Love* dealing with the artificial impregnation of a married woman with the semen of a man not her husband. Lastly, Mr. Charles questioned her regarding a work by her entitled *A New Gospel to All People*, from which he quoted. In the course of a long cross-examination by Sergeant Sullivan the plaintiff said there were many passages in *Married Love* which it would be an outrage to read aloud—passages written to be read with the book complete, in solitude and with a thoughtful mind. Asked about Bradlaugh's pamphlet, *The Fruits of Philosophy*, written by Dr. Knowlton, plaintiff said she did not think it obscene, but undesirable. Asked if there was anything in that pamphlet approaching the passages to which counsel had drawn attention in her book, she answered that it was dealing with a different subject. In reply to his Lordship, she said she had not ascertained what the word "obscene" meant in a legal sense. The method of contraception taught in her books could not be used by a virgin. Harmful and misleading information on the subject had been circulating freely in this country since 1823.

Maud F. Hebbes, a certified midwife, said she had been employed at the plaintiff's clinic in Holloway Road since March 17th, 1921. During that time 1,700 women had visited her with regard to birth control; no experiments were made there and she had never received a complaint from any woman attending. If they were having babies too quickly she taught them how to adjust the check pessary over the cervix, having herself first made a simple examination. She might never see them again (this in reply to Mr. Charles).

Sir William Arbuthnot Lane, Bt., F.R.C.S., consulting surgeon to Guy's Hospital, and a vice-president of the plaintiff's society, said that in the course of his practice he had seen intense misery and distress entirely due to multiple pregnancies. When he got to know the work of Dr. Stopes he felt he had come across a real and intelligent philanthropist at last. He had read all her books but had never been to her clinic. Assuming cleanliness there was no danger in the measures advocated at plaintiff's clinic. He had advised numbers of women to use the occlusive pessary. During cross-examination Sir W. A. Lane suggested to Mr. Charles that the preface to *Married Love*, by one of the most distinguished of living physiologists (Professor Starling), expressed the opinion of the medical profession as he (Sir William) knew it. He did not know, however, whether Professor Starling was coming to give evidence; nor whether Lord Dawson (whom Mr. Hastings had mentioned) was coming to give evidence. An expert midwife knew as much as a doctor about applying a check pessary.

Mr. Harold Chapple, M.Ch., F.R.C.S., obstetric surgeon and gynaecologist to Guy's Hospital, said he was quite familiar with the work carried on at plaintiff's clinic, though he had not visited it; he approved of her works and the things she advocated. In his opinion, the ordinary check pessary, if used with average intelligence, could not be injurious; he had never seen it do any harm. In a perfect world all such cases would be dealt with individually by a doctor. So far as the gold pin was concerned he had no knowledge of it from practical experience. In reply to his Lordship, who asked: "Is it your view, most sincerely held, that it is desirable that the public generally should know about the use of a check pessary?" the witness answered: "Yes; this is a woman's problem, and in particular, it is a married woman's problem." In order to go into the whole problem, when giving instruction about sex, it was necessary to talk about check pessaries. Sex education and contraceptives could not be separated. Closely questioned about extracts from the plaintiff's works, Mr. Chapple insisted that the sense of a book was lost if isolated passages alone were taken from it.

Sir William Bayliss, F.R.S., professor of general physiology at University College, London, said he was a vice-president of the plaintiff's society, and saw nothing objectionable in any of her books, which served a most excellent purpose of instruction in the matters of sexual relations. He had no personal knowledge of the clinic. He did not think there was any harm in teaching young people about the use of the check pessary; they would not be interested in it.

Dr. Meredith Young, M.O.H. for Cheshire, said he had read everything the plaintiff had ever written; and he adopted the words used by Mr. Chapple—that they were clean, well and beautifully written books with a high ideal. He considered the clinic extremely well and ably run. He could not see that any injury was to be apprehended from the use of the check pessary if employed in a proper manner by an ordinary intelligent person. In reply to Mr. Charles, he could not see that any harm could

result from the widest possible circulation of books like these. He was closely questioned about artificial insemination, and about the gold pin. He admitted that if conception took place the effect of the pin would be to produce abortion. Re-examined, he had had experience of very similar things, but not actually of the gold pin; it could only be used under medical supervision.

Dr. Janie Lorimer Hawthorne said she worked very largely among women and children and acted as honorary consulting surgeon for the plaintiff's clinic. She thought the effect of the plaintiff's books would be to help people to understand the marriage relationship; in her experience lack of such knowledge led to great unhappiness. She found nothing at all objectionable in any part of *Married Love*. Cross-examined, she thought a qualified midwife was quite capable of advising and fitting a check pessary. She had very little experience of the gold pin and therefore would not advise its use. She did not attend the clinic very regularly—perhaps once a fortnight; at each visit she saw perhaps three or four patients; perhaps six patients in a week were sent on to see her from the clinic during the intervals between her visits. Dr. Hawthorne was taken very closely over a publication by the plaintiff, entitled *A Letter to Working Mothers*, but maintained in effect that young people could come to no harm from reading this or *Wise Parenthood*.

Dr. George Jones, giving evidence, warmly praised the plaintiff's books, her clinic, and the midwife employed by her. He was emphatic that no possible danger attached to the use of the check pessary: the whole thing was "pure moonshine and nonsense." About the gold pin, of which he admitted he knew very little, Dr. Jones was closely cross-examined. In regard to the references to artificial insemination witness said that all knowledge was interesting, filth or no filth. Counsel remarked that if that be the true doctrine it seemed a little absurd to have a law against obscene publications. Witness replied that that law had gone a good deal farther than it ought to have done, and probably it would be altered as time went on: Common Law was always growing.

The Right Hon. G. H. Roberts, formerly Minister of Labour, said he had lived with the poor all his life, and, because of his appreciation of Dr. Stopes's work, took the chair at her meeting in the Queen's Hall in May, 1921; he had not visited her clinic. Cross-examined, he saw no objection to passages in her works indicated by counsel; normal girls and young men should, he thought, be educated in these matters; but he had never posed as an authority on particular methods. All depended on how the books were written; a book should be read as a whole.

#### Case for the Defence.

Mr. Charles, opening the case on behalf of Dr. Sutherland, said that, however conducted, the plaintiff's campaign was dangerous, and as conducted in this case it was monstrous. Hence she must not object to strong criticism. Dr. Sutherland had criticized the campaign but not the campaigner, against whom he had no malice at all. Neither Bradlaugh nor his colleague, Annie Besant, had gone nearly as far as plaintiff in her books. Counsel argued that Dr. Stopes's principal book was not merely a physiological treatise: it contained pages of common erotic stuff.

Miss Louise McIlroy, M.D., professor of obstetrics and gynaecology at the Royal Free Hospital School of Medicine for Women, said she had been a specialist in diseases of women since 1898. In July, 1921, she read a paper before the Medico-Legal Society, and in reply to the discussion she had said that the check pessary was the most dangerous form of contraceptive she knew of. In her opinion the unrestrained use of contraceptives without medical advice was extremely bad. Insertion of the check pessary might induce sepsis. If it did not fit the cervix it would not serve its purpose, and if it fitted the cervix it was liable to close up natural or unhealthy secretions. The use of a condom or sheath was not harmful to women. In cross-examination by Mr. Hastings, Professor McIlroy reiterated that she had known cases in which a woman could not have a child because of the previous use of artificial contraceptives. She agreed that there was a very large difference of opinion, both within the medical profession and outside it, about the advisability of using contraceptives. She was not opposed to contraceptive methods in medical cases; she recommended them in certain cases. In advising she considered the individual patient. She thought the plaintiff was genuinely trying to deal with the problem, but was misguided in her methods. In reply to his Lordship she regarded the use of contraceptives as being at most the second best. Her experience of occlusion of the womb was large, but did not include any case of a woman who had worn a check pessary. In reply to Mr. Hastings's questions about *Married Love*, she knew of women who were made miserable by their marital relations, but she did not think writing could do any good. Apart from individual cases, she agreed that it was possible to deal satisfactorily with the problem as a whole, but only in simple scientific language, not in a sympathetic and romantic strain.

Dr. Halliday Sutherland then gave evidence. He was taken over his medical career and his experience of practice and research in civil life at home and abroad, and in the Royal Navy and Royal Air Force during the war. As a result of what he heard at the Medico-Legal Society meeting on July 7th, 1921, he decided to study birth control and write a book on it; this was because he thought it good to make known to the public certain arguments against artificial birth control. He was a Roman Catholic, but it was not at the behest of any Roman Catholic that he wrote this book. Mr. Charles then asked the witness about the subject-matter of his book, and his observation of various public notices of the plaintiff's works. His book was published on March 27th, 1922; Dr. Stopes had written for a copy on March 24th, and a few days later it was sent to her. Her husband wrote on April 12th inviting witness to debate his views with their society. He sent no reply to the invitation because he did not want to do anything to further advertise plaintiff's campaign. The writ of libel was issued on May 12th. By the words "exposing the poor to experiment" he referred to the indiscriminate distribution of knowledge of artificial contraceptives among the poor for the purpose of attempting to redistribute the birth rate, contrary to the law of Nature: he considered this a bad social experiment. Further, from a medical point of view, the advocacy of the occlusive check pessary was harmful. By the words "a doctor of German philosophy (Munich)" he wished to make it perfectly plain that plaintiff was not a doctor of medicine and had no scientific degree which qualified her by knowledge to teach these methods; moreover, he had in mind that underlying this movement was a philosophy of materialism, associated since the war in a loose popular way with German philosophy. By "monstrous campaign" he meant the whole campaign—press campaign, books, lectures, interviews, and the clinic—and his point of view was both medical and national. He had never spoken to Dr. Stopes and felt no sort of personal malice against her. His reference to Bradlaugh meant that the movement should be stopped.

In the course of a long cross-examination by Mr. Hastings, Dr. Sutherland said he meant his book to be controversial. He claimed no gynaecological experience since 1907, but he had studied this question and written a book. Counsel read passages from witness's book and from a speech by Lord Dawson at the Church Congress, and witness said that what he had written about Lord Dawson's views was a piece of strong writing. He thought the question of the advisability and the disadvantages of contraceptives had been thrust upon the general public; the opinion of the British Medical Association, with which he agreed, was that the means of knowing of such things should be obtained through a doctor; indiscriminate broadcasting of that kind of knowledge would do no good. Teaching in regard to matters of sex should be individual, and children should, emphatically, not be told about contraceptives. He considered that Dr. Stopes in her writings on sex was most unfortunate, because these contained a nauseating mixture of physiology and emotion instead of the cold language of physiology; the good idea in *Married Love* (written with the very best intentions in the world) was absolutely spoilt by the unnecessary details that followed and by its indiscriminate distribution. He held the firm conviction that the poor were among the sanest people in this country in regard to sex. By indiscriminately spreading knowledge about contraceptives and starting a birth control clinic the plaintiff, in his view, had done a more serious thing than Charles Bradlaugh did. When he wrote to this effect in his book he knew the contents of the Bradlaugh pamphlet but had not read it. He recognized that plaintiff wished to restrict the population among the poor; he knew, too, that she wanted to get healthy children at the best times, but that could not be done. As to the word "experiments" he did not mean surgical experiments; but the fitting of poor women with the harmful check pessary was an experiment, and the whole thing was a social experiment. In re-examination witness said he had collected a great deal of literature on the subject before writing his book. Lord Dawson had made no complaint whatsoever about what he (Dr. Sutherland) wrote; he understood that Lord Dawson disapproved of the indiscriminate broadcasting of information about these contraceptives.

Dr. A. E. Giles, senior surgeon to the Chelsea Hospital for Women and consulting gynaecologist to the Prince of Wales's Hospital, Tottenham, said that the so-called check pessary (handed to him in court) was intended to cover up the cervix completely so as to close its orifice. Were the instructions given in *A Letter to Working Women* carried out effectually there might or might not be danger according to the woman's condition at the time; unhealthy secretions would tend to be drawn back into the system, with a chance of great inflammation. It was difficult to understand how a woman could fit this pessary properly for herself, and a nurse or midwife was certainly not capable of saying whether a woman ought to use it or not; it should only be fitted by a doctor who thought it safe and proper after satisfying himself there was no disease. The gold pin or wish-bone pessary was advertised by

its makers as favouring conception; if conception occurred with it in place a miscarriage would be the almost certain result; it would be dangerous for a woman to wear it for any length of time, and it might affect her future fertility. Cross-examined, Dr. Giles said it would be very difficult for anyone not a doctor to apply the gold pin. In reply to the judge, he thought a skilled female abortionist could insert it, though she was likely to do very great damage thereby.

Dr. F. J. McCann, surgeon to the Samaritan Hospital for Women, maintained that the general effect of artificial contraceptives was contrary to the best interests of a woman's health. Assuming that the check pessary was properly placed and doing the work for which it was intended, there would be chronic uterine congestion with a subsequent impairment of fertility. To broadcast this device and the quinine pessary would be most injurious. The gold pin hindered but did not stop conception; it was a dangerous abortifacient; he had removed one which had been fifteen months in the cavity of the uterus, causing a discharge. Cross-examined, witness said he held a very strong view, on national grounds, against the use of contraceptives save for reasons of health—in the presence of disease. He was closely questioned regarding his personal experience of any women who had been injured in health by the use of a rubber check pessary, and he gave details of one case in which he attributed menorrhagia to congestion arising from this cause. In his view all contraceptive methods used by women were injurious.

Mrs. Mary Scharlieb, M.D., consulting gynaecologist to the Royal Free Hospital, and consulting surgeon to the New Hospital for Women, expressed the view that if the instructions and advice as to the check pessary given in *Wise Parenthood* were applied to women damage was likely to follow, because it would restrain the natural secretions, and lead to a mild continuous sepsis if retained *in situ*. She believed the gold pin to be exceedingly dangerous; it was not so much a bar to conception as an instrument likely to cause very early abortion; if retained for months (as the book said it might be) and the woman aborted, this was too likely to be a septic abortion. Cross-examined, Dr. Scharlieb had no doubt as to the plaintiff's sincerity and good intentions, but held that no useful work had been done by publishing these books; she had read them all and objected to them all. In writing a few lines introductory to *Wise Parenthood* she had said that she differed entirely from the author regarding the views expressed, and the author acknowledged her disagreement. In her view the enlightenment of the public was imperative, but this should be undertaken in perfectly simple non-provocative language; it should not be emotional, nor make any appeal to the passions. Re-examined about a letter she had written to plaintiff's publisher, she repeated her opinion that the encouragement of people to use artificial contraceptives was materialistic—a thing that grieved her.

Dr. Norman Haire, who attended on subpoena, said, in reply to Mr. Rabagliati, that he was an obstetric and gynaecological surgeon now practising in London. He held the post of honorary medical officer in charge of a welfare centre in Watworth, where, besides ordinary welfare work, birth control knowledge was given by a doctor to all married women who desired it. He had written on this subject. In 1921 he went to plaintiff's clinic and discussed the gold pin. After that he made further inquiries which led him to judge that the pin would be unreliable and dangerous. He wrote to her expressing admiration for her work and begging her not to recommend a thing that might be dangerous. He was strongly in favour of a medical man or woman conveying knowledge of contraceptives to all married women. Dr. Haire was cross-examined by Mr. Hastings as to his communications with plaintiff about patients; he might have said he would be pleased to see any further patients she cared to send, but he had in no way canvassed for patients. He still thought her books served a very useful purpose, though he did not agree with all her points of technique, and he disagreed very greatly with the *New Gospel to All Peoples*. He used to recommend and fit the check pessary in appropriate cases, but found that women could not reintroduce it properly, so he gave up advising it. He had seen cases in which harm had followed its use, but he could not say that this was due to its use.

Mrs. Agnes Savill, M.D., said she was a general physician dealing largely with electrical treatment, and in the course of her experience had seen two unmarried women, one aged 25 and the other 40, whose health had been adversely affected by reading *Married Love*. Cross-examined, she did not think the book could do harm to married people; but it was making a natural function like eating and drinking a high art; it made married people think too much about sexual details; it was like a gourmand with food.

Dr. William Ernest Falconar, physician to out-patients, Paddington Green Children's Hospital, said he disliked very much the contraceptives advocated by the plaintiff. At the end of last September a young woman brought him a gold pin, asking him to insert it, and handed him a copy of *Wise Parenthood*. Having examined the pin he pointed out the danger and refused to insert it; he regarded it, not as a contraceptive, but as an abortifacient.

Sir Maurice Abbot Anderson, M.B.—whose evidence was taken on commission, by reason of ill health—stated that, broadly speaking, he favoured some sort of contraceptive procedure up to a point, but not that which the plaintiff advocated.

This concluded the case for the defendant, no evidence being called on behalf of Messrs. Harding and More, publishers of the book. Serjeant Sullivan then addressed the jury for the publishers, Mr. Charles for Dr. Sutherland, and Mr. Hastings for the plaintiff.

#### *The Summing Up.*

In the course of his summing up the Lord Chief Justice pointed out that the plaintiff—a lady of remarkable ability—was bringing this action to recover damages for a particular piece of writing which she said was a libel upon her. The passage complained of was a particular passage, with some omissions, in one of the later chapters of a book purporting to be a general examination of the problem of what was called "birth control." His Lordship reminded the jury of certain dates. The plaintiff's two chief works were published in 1918, one in the spring, the other in the autumn. In March, 1921, she opened the clinic. A few months later Professor McIlroy addressed the Medico-Legal Society on some topics connected with birth control. Dr. Sutherland's book was published on March 27th, 1922. Plaintiff's husband wrote to Dr. Sutherland inviting him to take part in a public debate, and a review of the work appeared in plaintiff's paper on May 3rd. Then, without any further warning, no letter before action, no remonstrance, there came upon May 12th the writ in this action. The defendants in their defence admitted publication, but said that so far as concerned statements of fact in what was complained of, those were true statements; so far as concerned expression of opinion, that was fair comment. It was not denied here that the subject-matter of this discussion was matter of public interest. Where the plea "This is true" was put in, that plea must in the proper and reasonable sense cover all the allegations of fact. This did not mean that every little detail had to be established, but that the gist of the libel—the real sting—must be established. In regard to the defence of fair comment the question for the jury was not at all "Do you agree with the criticisms the defendant has written?" but rather "Could a fair-minded man holding a strong view, holding perhaps an obstinate view, holding perhaps a prejudiced view—could a fair-minded man have been capable of writing this?" But the foundation of the structure upon which fair comment was to be built must be a foundation of truth: "a man cannot invent things, call them facts, and then base comment which shall be fair upon them as if they were facts." Two ingredients were needed: true statement of fact; and, upon the statement of fact, comment which a reasonable fair-minded man might make, whether the jury agreed with him or profoundly disagreed with him.

Now in this case the phrase "birth control" had been used in many different senses: but some precision of thought was necessary. Nobody so far as this case was concerned disputed for a moment the wisdom of explaining in innocent helpful language to young persons of both sexes some of the mysteries and implications of sex. Once depart from this admitted truth and the region of controversy was entered. Controversy began with the question of what should be the method of making these truths known. In much of the evidence that had been given, the next step seemed to be taken by a kind of jump: because it was desirable that young people should be taught in an innocent and pure-minded fashion the truth about sexual matters, therefore it was important that they should be taught the truth about what were called contraceptives. The next step was a further jump: because contraceptives were desirable for some persons in some circumstances, therefore everybody should be taught about them. Then it became at the next step a duty to differentiate between contraceptives; and then they came down to the check pessary. So that, starting from the large general unobjectionable statement that somebody, speaking to one person in private, should instruct the young innocently upon the implications of sex, it became a sort of public duty to spread about on the widest possible scale, without discrimination of sex or age, or marriage or absence of marriage, the truth about the check pessary; and the check pessary, when that stage of the argument was reached, had become something like a talisman, a goal, or a standard—a panacea for social ills, both public and private. There obviously were those who held that view. But might there not be those who stoutly held the opposite view: who said that these were matters of great delicacy and difficulty, that contraceptives might be in some cases a deplorable necessity, but that this information ought not to be published broadcast to all and sundry, and that, if so published, great care should be taken with the language, tone, and manner employed? It might have occurred to the jury that if the whole object was to diffuse as widely as possible the important truth that with the help of a check pessary a man and a woman

need never have a child—might not that information be put in words of two or three syllables on half a sheet of notepaper? Whatever might be the mischief of broadcasting such information, that mischief (said many of the witnesses) was greatly exaggerated when the information was conveyed in a romantic, emotional, rhetorical fashion. There being thus profound differences of opinion, was it not plain that these might with vigour and vehemence be expressed?

His Lordship next examined the general purpose and arrangement of the defendants' book and the extracts from it which had been made the subject of these proceedings. He completed the second extract by quoting the words omitted in the plaintiff's statement of claim. In its complete form the second part of the passage ran:

"When we remember that millions are being spent by the Ministry of Health and by Local Authorities—on pure milk for necessitous expectant and nursing mothers, on Maternity Clinics to guard the health of mothers before and after childbirth, for the provision of skilled midwives and on Infant Welfare Centres—all for the single purpose of bringing healthy children into our midst, it is truly amazing that this monstrous campaign of birth control should be tolerated by the Home Secretary. Charles Bradlaugh was condemned to jail for a less serious crime."

His Lordship then discussed at some length the meanings put upon the word "experiment" by the plaintiff and by the defendants, and in this connexion reviewed the medical evidence regarding the "gold pin." He then touched on the other phrases alleged to be libellous, and noted the difference of opinion among the medical witnesses in regard to the check pessary. Coming to the closing words of the passage complained of, he observed that the plaintiff said these amounted to an accusation of crime, whereas the defendant said that what he meant was, "Here is the Home Secretary tolerating something which is really worse than that which in the case of Charles Bradlaugh was held to be a crime." Whether they thought these words imputed criminality or not, the jury ought not to draw an inference from the fact that there had been no prosecution with regard to the plaintiff's books. In the Bradlaugh case the charge was the publication of an obscene book. At this point his Lordship made some observations on the meaning of the word "obscene," and continued:

Now what is said here? Dr. Sutherland says that this is as bad as the Bradlaugh pamphlet and worse; and he says that in two respects. You have passages, he says, in these books to which no parallel can be found in the pamphlet published by Mr. Bradlaugh—no parallel at all. Your attention has been directed to certain passages; I am not going to re-read them to you. I daresay you have taken the trouble to read, as I have done, other passages. But just consider. The argument is that these are books which may be exposed for public sale indiscriminately, in great quantities, in order to fulfil a mission. The mission is variously described at various points of the argument. The teaching about sex is mixed up with the teaching about contraceptives; the teaching about contraceptives is mixed up with other matter; but it is all said to have been done in pursuance of a mission.

Whatever view the jury took about that question, they might ask themselves what legitimate purpose could be fulfilled by the insertion in these books—to be read by married and unmarried, young and old, persons of both sexes—of passages that described certain matters relating to sexual intercourse and analysed others. The jury knew the passages, knew the context, knew the circulation of these books. Could they say that these fell short of being obscene publications?

#### *Verdict and Judgement.*

The jury, after considering their verdict for three hours and three-quarters, returned the following answers to the questions put to them by the Lord Chief Justice:

- (1) Were the words complained of defamatory of the plaintiff?—Yes.
- (2) Were they true in substance and in fact?—Yes.
- (3) Were they fair comment?—No.
- (4) Damages, if any?—£100.

Counsel for the plaintiff and for the defendants each formally claimed judgement for their clients, and on the following morning his Lordship heard argument on the legal effect of the findings of the jury. Sir Hugh Fraser maintained that plaintiff was entitled to judgement for £100. Mr. Charles submitted that on the answers to judgement for £100. The defendants were, by every rule of law, to the first two questions the defendants were, by every rule of law, entitled to judgement; the plea of justification was a complete answer to the action; if the words were true, there was an end of the matter. Serjeant Sullivan argued that a plea of fair comment did not arise if a plea of justification was made good.

His Lordship, in giving judgement, said he always understood that it was a good defence in libel if the words complained of were true in substance and in fact. On the findings of the jury in this case there was no course open to him but to give judgement for the defendants.

Mr. Charles asked for costs and these were granted; his Lordship agreed also to Sir Hugh Fraser's request for a stay of execution on the usual undertaking.

## The Services.

### TERRITORIAL DECORATION.

THE Territorial Decoration has been conferred upon the following officers of the R.A.M.C.(T.A.): Colonel F. W. Higgs, C.B.E., Major H. L. Gregory, Major S. R. Gibbs, M.C., and Major D. Shannon.

### FOREIGN DECORATIONS.

THE following decorations and medals have been awarded by the Allies indicated for distinguished services rendered during the war 1914-19, and the King has given unrestricted permission for them to be worn:

By the President of the French Republic: *Médaille de la Reconnaissance Française en Argent*—Lieut.-Colonel John Miller, D.S.O., M.C., R.A.M.C.(T.F.).

By the King of Italy: *Order of St. Maurice and St. Lazarus*—Commander: Major-General Sir Foster R. Newland, K.C.M.G., C.B., retired pay; Officer: Colonel John Vincent Forrest, C.B., C.M.G., retired pay; Cavalier: Captain Thomas Douglas Inch, O.B.E., M.C., R.A.M.C. (R. of O.). *Order of the Crown of Italy*—Officer: Brevet Colonel Arthur Chopping, C.B., C.M.G., R.A.M.C.; Cavalier: Temporary Captain Ambrose Emerson, R.A.M.C.

## Medical News.

THE Senatus Academicus of the University of Aberdeen proposes to confer the honorary degree of LL.D. on Sir George Henry Makins, G.C.M.G., C.B., consulting surgeon to St. Thomas's Hospital.

PROFESSOR G. ELLIOT SMITH, F.R.S., will give the foundation oration of the Union Society of University College, London, on Thursday, March 22nd, at 8.30 p.m.

THE Denison House Committee on Public Assistance is about to present a petition to the Prime Minister asking for information as to the growth of expenditure from rates and taxes on public assistance and for a commission of inquiry and control. The expenditure, which in 1890 was 25 millions, had risen in 1920 to 233 millions, excluding 93 millions for war pensions. The expenditure on education in 1920 was 72 millions.

THE Medical Women's Federation has arranged to hold a dinner in the Empire Rooms, Trocadero Restaurant, on Thursday, May 10th, at 7.30 for 8 p.m.

A MEETING of the Tuberculosis Society will be held in the Council House, Bristol, on Friday, March 16th, at 10 a.m. At the morning session, tuberculosis and pregnancy will be discussed by Professor Lyle Cummins and Dr. E. Ward; and reactions relating to tuberculosis by Drs. Henry Ellis and Campbell McClure. At the afternoon session, the physique of the phthisical will be discussed by Dr. H. de Carle Woodcock; difficulties in diagnosis by Drs. Halliday G. Sutherland, T. Nelson, and Richard Clarke; and the domiciliary treatment of osteo-articular tuberculosis by Dr. W. C. Rivers. On March 17th at 10 a.m. Dr. T. Nelson will demonstrate the results of treatment by artificial pneumothorax.

THE London County Council has hitherto employed a woman doctor to examine, under the direction of the medical examiner (Sir John Collie), all women candidates selected for appointment on the staff of the Council or as school nurses, and any women members of the staff who were required to undergo medical examination and desired to be seen by a woman doctor. Mrs. Dickinson Berry, who has held this appointment for some years, having resigned, it has been decided to appoint a panel consisting of three women doctors, so as to obviate the inconvenience from any one part-time woman doctor being not always available. The medical examiner, who will be responsible for their certificates, and under whose direction the examinations will be made, proposes to pay them not less than 75 per cent. of his fee in each case.

AN Act has been passed in Spain giving the Spanish Government powers to proceed with the ratification of the "Maternity Convention" adopted by the first international labour conference held at Washington, under the auspices of the League of Nations, in 1919. Under the terms of this convention a woman who works for her living is not allowed to work during the six weeks following confinement, and has the right to leave her work six weeks beforehand on production of a medical certificate. During this time she is paid benefits provided either out of public funds or by means of a system of insurance, and is also entitled to free medical attendance; if nursing her child she is allowed half an hour twice a day during working hours for this purpose. The same Act authorizes the Spanish Government to institute a compulsory maternity insurance system. The "Maternity Convention" has already been ratified by Italy, Bulgaria, Greece, and Rumania.

ON March 3rd, at the Medical Society's rooms, Bournemouth, the members of the Dorset and West Hants Branch of the British Medical Association presented Dr. Walter Asten with an illuminated address, an armchair, and a selection of books on the occasion of his leaving Bournemouth, as a mark of their appreciation of his services as honorary secretary of the Branch during the last four years.

ON Friday next, March 16th, Sir Leonard Rogers will read a paper at 4.30 p.m., before the Dominions and Colonies and Indian Sections of the Royal Society of Arts, on recent advances towards the solution of the leprosy problem. The chair will be taken by Earl Winterton, Under Secretary of State for India.

AT a meeting of the Medico-Legal Society on Tuesday, March 20th, Dr. H. A. Burridge, lecturer on forensic medicine and toxicology at King's College Hospital, will open a discussion on State effort to rescue drug victims, with special reference to the Dangerous Drugs Act. The meeting will be held at the house of the Medical Society, Chandos Street, Cavendish Square, at 8.30 p.m.

THE first regional centre of the campaign against cancer in France was inaugurated by M. Strauss, Minister of Hygiene, at Bordeaux, on February 12th. It has been organized in the medical electricity department at the St. Raphael annexe of the Bordeaux Faculty of Medicine, under the direction of Professor Bergonié.

AMONG the courses of lectures arranged by the National Health Society is one of six on infant and child welfare by Dr. Eric Pritchard; the first will be given on Friday, April 20th, at 5 p.m. Dr. Mary Schärlieb will give the second of two lectures (for women only) on venereal diseases on Thursday, March 15th, at 4.30 p.m. Full particulars can be obtained on application to the Secretary of the Society, 53, Berners Street, W.1.

WE regret to announce the death, on February 20th, of Sir Thomas Roddick, M.D., F.R.C.S., who was President of the British Medical Association when it held its Annual Meeting in Montreal in 1897.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 43, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Litology*, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL ASSOCIATION, *Medical Assoc*, Bacillus, Du. F. Rutland; telephone, 4361, Central).

### QUERIES AND ANSWERS.

A MEDICAL man, aged 62, with high blood pressure and arteriosclerosis, who must not visit, seeks advice (1) as to the best locality to live in, and (2) the most suitable employment in order to make a living.

"J. R." asks whether the tetanus bacillus or its spores has ever been found in commercial milk, fluid or dried, and whether milkers and dairy workers are ever infected.

### SEVERE REACTION TO MOSQUITO BITE.

"X" (who resides in Wiltshire) writes: A lady, aged 50, suffers severely whenever bitten by a mosquito; within a few hours there is considerable oedema of the part, and at the site of the puncture a large blister forms, about the size of a pigeon's egg, which breaks, leaving a raw surface, just as after a scald. As the neighbourhood is never free from stray mosquitoes, the patient's susceptibility is becoming a serious matter, for whenever she is bitten on the leg she is compelled to lie up for several days until the oedema has gone and the blister has healed. While it is not practicable to protect her from occasional bites, "X" would be glad of suggestions as to how he may prevent these severe local reactions.

## EXAMINATION FOR DIPLOMA IN PSYCHOLOGICAL MEDICINE.

A CORRESPONDENT who proposes to sit for the examination in psychological medicine asks for suggestions as to books which would give a beginner a grasp of the subject and the new nomenclature used in psychology.

"\* The knowledge required must depend on the examination contemplated. The requirements for the diplomas in the various universities and the London Conjoint Board vary to some extent, but with all a wide range of reading is necessary. A good clinical knowledge of psychiatry and neurology, as well as of asylum administration, is also necessary. For these diplomas a course of instruction such as that given at the Maudsley Hospital or Bethlem Hospital is almost imperative, as practical examinations are held in anatomy and physiology of the nervous system, psychology, clinical psychiatry, and neurology. The following books for psychological medicine may be recommended:

## GENERAL PSYCHOLOGY.

*Psychology: A Study of Mental Life*, By R. S. Woodworth. Methuen and Co.

*Psychology: The Study of Behaviour*. By Wm. McDougall, Home University Library. Williams and Norgate.

## ABNORMAL PSYCHOLOGY.

*The Psychology of Insanity*. By B. Hart. Cambridge University Press.

*Medical Psychology*. By T. W. Mitchell. Methuen and Co.

## TEXTBOOKS OF PSYCHIATRY.

*Mind and its Disorders*. By W. H. B. Stoddart. Lewis and Co.

*Mental Diseases*. By R. H. Cole. University of London Press.

*Psychological Medicine*. By Sir Maurice Craig. J. and A. Churchill.

A textbook of neurology should be read, and works giving an account of the anatomy and physiology of the nervous system.

## INCOME TAX.

"A. F. M. B." puts the case of two partners, A and B, the practice being divided on a two-thirds and one-third basis. The firm rents A's surgery from him, and also uses B's house and a room or two of the remainder of A's premises. What can be claimed for rent and rates, etc.?

"\* (1) The surgery rent paid to A, (2) the actual cost of lighting, heating, and cleaning it, (3) a reasonable proportion of the total expenditure on B's house and the remainder of A's. On the facts B does not seem entitled to a proportion of one-half, and A's proportion of the remainder of his house must clearly be less than half. A test of the reasonableness of the amount charged as (3) might well be that it should be such a figure as would bring the total to approximately one-half of the total costs of A's house and surgery and B's house together.

"Novice" inquires what proportion of the following can be claimed as professional expenditure: (1) Rent, rates, etc., of house; (2) man's wages; and (3) maid's wages.

"\* Assuming that "Novice" is in general practice, the answer depends legally on the third rule applying to Cases I and II, Schedule D; this rule excludes expenses of maintenance of the person assessed and his family, etc., or for private as distinct from professional purposes, and the rent paid for such part of the house, etc., as is not used professionally. In practice a useful working rule is that in the average case half the rent and the board and wages of one maid are considered allowable. When a man is kept to drive the car a proportion of that expense should be charged based on an estimate of the time he spends on professional as distinct from private duties.

## Car Transactions.

"J. A." who sold his old car in January for £80 and bought a new one for £100, can deduct £20, less the amount, if any, by which £400 exceeded in January the cost of a car similar to the old one. As the expense was incurred in January of this year it does not affect the calculation of the average profits forming the assessment for 1922-23; it is an admissible professional expense in the ordinary way—for example, if "J. A." makes up his accounts as at the end of March it will first affect the income tax average for the financial year ending April 5th, 1924.

"C. R. J." bought a Morris coupé in 1918 for £360; at that period he was using a cycle when the car was undergoing repair. He then (in 1921) bought a 8-h.p. Rover for £235 to replace the cycle, and it is used both privately and professionally—say half and half. He now proposes to sell the Rover for £110 and buy another Morris four seater for £355, keeping the old one in reserve.

"\* While the old Morris car is retained the cost of the new one represents capital outlay. Assuming that the expense of purchase of the 8-h.p. Rover was not changed, and that only one-half the running cost was deducted for tax purposes, the amount of deduction that can now be claimed is half of (£235 - £110) = £62 10s., which is the extent to which the cost of the new Morris car represents replacement of professional equipment.

## LETTERS, NOTES, ETC.

## SMALL-POX AND VACCINATION IN THE PHILIPPINES.

We have received from the President of the Council of Hygiene of the Philippines a letter enclosing a copy of a report on small-pox and vaccination, the occasion being the publication in the BRITISH MEDICAL JOURNAL and elsewhere of comments on the position in the islands. The letter is dated January 19th, so that the detailed examination and analysis by Dr. McVail of the facts as disclosed by the Reports of the Philippines Health Service, which appeared in our issue of January 27th, cannot have been seen by the Council, but only the earlier notices in the JOURNAL. We are therefore intimating to the President our intention to defer dealing with the matter further until the Council have had the opportunity of seeing the JOURNAL of January 27th (which is being posted to Manila) and furnishing any further facts.

## HICCUP.

DR. J. D. GIMLETTE (Bath) tells us that an old-fashioned method of treating hiccup which he has found useful is for the patient to stop his ears tightly with his fingers and gulp down a glass of water while a friend pinches his nostrils.

"C. K." has noted an unusual prevalence of hiccup recently in his neighbourhood (in the Midlands). During the last six weeks he has seen five troublesome cases; continuing for twenty-four to forty-eight hours. Two of the patients were octogenarians, two were practising solicitors, and one a young postman. He has heard of two other cases; both middle-aged men, occurring in the same district. In four of the five cases under his care after simple remedies had failed relief quickly followed small doses of morphine and atropine by the mouth. In only one of the cases (the postman) was there any concomitant disease—a febrile cold.

MR. PERCY BLUMER, F.R.C.S. Edin. (Muswell Hill), writes: In the BRITISH MEDICAL JOURNAL of March 3rd, p. 402, I read Dr. Wm. Bramwell's note on his treatment of persistent hiccup. Late on the same evening a patient came to consult me complaining of hiccup, which had been troubling him for several hours, and nothing that he had tried had given him relief. I applied pressure with the stethoscope to the ensiform cartilage for about four or five minutes. The result was immediate relief, and there was no return when the pressure was removed. I met the patient's wife the next morning, and she informed me that her husband had had a good night and had gone to business as usual.

DR. ELEANOR E. BOURNE (Carlisle) writes: With reference to the remedy for hiccup by drinking out of the far side of the glass, this method was invariably employed by our family when children, and was described as "drinking water backwards." We never experienced any difficulty in the act, simply applying the mouth to the far side of the glass and bending head and body forwards and downwards from the hips; I was amused at the contortions, such as lying across a bed and hanging the head downwards over the side, considered necessary by some of your correspondents. The remedy must be an old-fashioned one, as it was handed down to us from my grandmother, who probably knew it before her arrival in Australia, about 1850. I have considered the effect due to the stimulation of the higher centres, owing to unusual co-ordinative impulses being necessary by reason of the unaccustomed attitude, and perhaps partly to a slight compression in the diaphragmatic area from the act of bending forward.

## WHOOPIING-COUGH.

DR. W. J. MIDELTON (Bournemouth) writes: I treat all my cases by painting the chest once a week with lin. crotonis (B.P.) or ol. crotonis co., which contains some cantharides; front and back alternately. I have never failed to cure a case by this means within one month.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 36, 37, 40, 41, and 42 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 63.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE  
BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Whole double column	...	...	3 15 0
Half single column	...	...	10 0 0
Half page	...	...	20 0 0
Whole page	...	...	...

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 472, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postal restante letters addressed either in initials or numbers.

## Hunterian Lectures

ON

## MAN'S POSTURE: ITS EVOLUTION AND DISORDERS.

GIVEN AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

BY

PROFESSOR SIR ARTHUR KEITH, F.R.C.S., F.R.S.,  
CONSERVATOR OF THE MUSEUM.

[Abstracts.]

## LECTURE I.—THEORIES CONCERNING THE EVOLUTION OF MAN'S POSTURE.

The true story of how anatomists abandoned the belief that man's body was a special creation and became converted to the theory of evolution commences in 1809, the year of Darwin's birth—when England and France were striving for mastery in the Spanish peninsula. The new idea was born in Paris—not, as one might well expect, in the famous schools of human anatomy hid amongst the crowded streets on the south bank of the Seine, but in the Museum of Natural History, situated in the neighbouring Jardin des Plantes. Three officials of the Museum—Cuvier, the Professor of Comparative Anatomy, Geoffroy St. Hilaire, who had charge of the collection of Vertebrate animals, and Lamarck, who was responsible for the Invertebrata—were effecting, amidst war and political change, a complete revolution in man's conception of the animal kingdom.

In 1809 the magnificent Cuvier, then in his fortieth year, standing, so far as concerned the public eye, head and shoulders above his colleagues, was bringing together the material for his famous work on *Ossements Fossiles*, awakening men to the knowledge that boundless ages of teeming life had come and gone before the present era began. While Cuvier was thus unconsciously enlarging man's conception of the past, his colleague, Geoffroy St. Hilaire, somewhat Cuvier's junior in years, was seeking for the common plan or design on which the bodies of vertebrate animals were built, thus preparing the way for those who were to preach the doctrine of a common descent for all living things. Lamarck, the least favoured of the three in the estimation of the learned men of his time, was twenty-five years Cuvier's senior. In the bustings of contemporary science he could scarcely make his voice heard, but we now know he had probed deeper into the secrets of Nature than either of his two colleagues. All his life long he had been a retiring but systematic student of living things and of the conditions under which they live. He was already an old man—a man of 65—when in 1809 he published two small volumes under the title of *Philosophie Zoologique*, in which we see that this retiring pioneer, as a result of a half-century of patient study, had reached the conviction that all the living things to be found on the earth to-day were but the twigs of a common tree of life, whose branches, trunk, and root were buried deeply in the past ages of the world. It is in this work, written in the seclusion of the precincts of the Museum, away from dissecting-rooms, and during stirring years of war, that we find the first clear statement of the belief—now universally held by human anatomists—that man's posture of body has been evolved from one which was simian or ape-like.

## LAMARCK'S THEORY.

To do Lamarck full justice it would be necessary to make lengthy extracts from those chapters which deal with the evolution of man, but the following quotation (vol. i, p. 349) will give a just estimate of the manner in which he explained the evolution of man's posture:

"Indeed, if any race of primates (quadrumanes) whatsoever, particularly the more highly evolved of them, were to lose, either from force of circumstances or any other cause, the aptitude for tree climbing and other such uses with their feet, as with their hands, the individuals of this race, for a series of generations, would use their feet only in walking, and cease using their hands as feet; then there is no doubt, from the evidence produced in the foregoing chapters, that these apes would finally be transformed into man (Bimanes), and that the great toe would no longer be separated from the other toes like a thumb, the feet serving merely the purposes of progression."

From this passage we see that, in the first place, Lamarck supposed man to have been evolved from a chimpanzee-like anthropoid, for we know that of modern and living anthro-

poids he regarded the chimpanzee as "the more highly evolved." The gorilla, it may be mentioned here, was not discovered until 1847—eighteen years after Lamarck had been laid in his grave. In the second place we note that Lamarck regarded the erect posture as a result of the chimpanzee-like ancestor having abandoned an arboreal mode of life for one in the open country. In the third place we note that he held the belief—one which we still regard as unproven—that the progress made by one generation in accommodating itself to an erect posture would, age upon age, be transmitted to the next generation. He was fully alive to the fact that any anthropoid which had acquired the human mode of progression had gained an enormous advantage; it would no longer be confined to tracts of tropical jungle but would have the whole length and breadth of the earth open to it.

## DARWIN'S THEORY.

Lamarck was a pioneer, but so far as concerns the evolution of man he did not induce a single anatomist of his own or of a succeeding generation to follow in his footsteps. We have to pass to the year 1871, when the *Descent of Man* was published, to find the first effective step in the development of our modern knowledge of man's evolution. The Philosophy of Zoology had remained sixty-three years in neglect, and Charles Darwin, who declared he had read and studied the book to no profit, was then 62 years of age. We turn at once to the *Descent of Man* to see what conception Darwin had formed concerning the evolution of the human posture. At page 76 of the first edition the following passage occurs, which contains an explicit statement of Darwin's explanation:

"As soon as some ancient member (elsewhere defined as some species of anthropoid like the chimpanzee) in the great series of the Primates came to be less arboreal, owing to a change in its manner of procuring subsistence, or to a change in the surrounding conditions, its habitual manner of progression would have been modified, and thus it would be rendered more strictly quadrupedal or bipedal. . . . Man alone has become a biped; and we can, I think, partly see how he has come to assume his erect attitude, which forms one of his most conspicuous characters. . . . As the progenitors of man became more and more erect, with their hands and arms more and more modified for prehension and other purposes, with their feet and legs at the same time transformed for firm support and progression, endless other changes in structure would have become necessary. The pelvis would have to be broadened, the spine peculiarly curved, and the head fixed in an altered position, all which changes have been attained by man. . . . It is very difficult to decide how far these modifications are the result of natural selection and how far of the inherited effects of the increased use of certain parts, or of the action of one part on another. No doubt these means of change often co-operate."

When the explanations advanced by Lamarck and by Darwin are compared it is at once seen that, as regards the manner in which the human posture has been evolved, there is much in common. (1) Both supposed that man had been evolved from a chimpanzee-like anthropoid and in the course of evolution the anthropoid posture had become human. (2) Both agree that the transformation had been initiated by a change from an arboreal to a terrestrial mode of existence. (3) Both believed that the results of habit or of function, acquired by one generation, could be inherited by the next generation. Darwin, however, made important additions: (1) he applied the law of natural selection—the tendency for successful individuals to survive and prosper; (2) he recognized the action of sexual selection; (3) he perceived that there was a law of correlation of parts—an obscure mechanism by which a number of structures were modified together to suit some particular function of the body. We now realize—or rather begin to realize—that the development and modification of various systems of structures are regulated or influenced by various internal secretions or "hormones." Darwin's law of correlationship of parts is but an intelligent anticipation of the more recent discoveries of physiology. We expect that fuller knowledge will yield the key to many problems in the evolution of posture which are at present unexplained.

In their bald outlines the explanations given by Lamarck and by Darwin of how man came by his erect posture have much in common. Why was it that for sixty-two years the one was regarded as an idle curiosity, while in the course of ten short and strenuous years the other had spread into every anatomical workshop throughout the civilized world, revolutionizing the worker's point of view and endowing his labour with a new aim and a new zeal? Both *Philosophie Zoologique* and *Descent of Man* were founded on a lifetime of inquiry and observation, but Darwin conquered—as men always will conquer—because he permitted a masterly array of facts to tell their own story, while Lamarck always wished

to tell the story of his facts. However that may be, there is no doubt of the fact that the *Descent of Man* is the starting point of our modern knowledge of all that pertains to the origin and evolution of the human body. The student of history will also note the fact that neither Lamarck nor Darwin was a professional anatomist, and yet they did more to alter our conception of the human body than any professional anatomist of their time.

#### How the Theory Now Stands.

Much has happened in the fifty-two laborious years which followed the publication of the *Descent of Man*. The time has come, so it seems to me, for a fresh survey of our knowledge of all that relates to man's posture in order that we may ascertain how far it is now necessary to modify, extend, or amplify Darwin's explanation of its evolution. My aim in this lecture is to pass in brief review recent inquiries and investigations which throw fresh light on how, when, and where man came by his erect attitude. I have also another object in view—to show that the problems relating to the evolution of posture have a very direct bearing on medical and surgical practice; many of the obscure and distressing conditions which require treatment are in reality manifestations of a disturbance or derangement of the elaborate mechanism which regulates and maintains the remarkable posture of the human body.

#### EVIDENCE FROM FOSSIL REMAINS.

The fossil remains of man, so far as they have become known to us in recent years, do not provide any certain clue as to the date, place, or manner in which the human posture was evolved. We cannot say that any fossil form of man yet discovered shows a foot in a stage intermediate to that of anthropoid and man. The most important discovery for our present purpose is that made by Dr. Eugène Dubois during 1891 and 1892 when he was resident in Java. He discovered the remains of a strange and distinct genus of man, to which he gave the name of *Pithecanthropus erectus*. No part of the foot, leg, or trunk was found, only three teeth, the roof of the skull, and the left thigh bone. The thigh bone leaves us in no doubt as to the posture of body; it is human in all its characters; we cannot explain its characters unless we suppose that *Pithecanthropus* was human in posture and gait. The stratum in which the remains of *Pithecanthropus* were found belongs either to the beginning of the geological epoch which precedes the present—the Pleistocene—or to the end of the still older epoch—the Pliocene. We thus know for certain that the human posture was fully evolved at least before the beginning of the Pleistocene period. There are many reasons, however, for supposing that *Pithecanthropus* represents a persistence of a primitive type which had appeared long before the beginning of the Pleistocene; in size of brain we must regard him as representative of man at the beginning rather than at the end of the Pliocene period. The thigh bones show that the lower extremities were used as in us, but the characters of the skull are incompatible with the poise of head seen in modern man. In the fossil man of Java the head was hinged to the neck as we see in living anthropoids—so that the head is carried with a forward slouch.

In recent years we have greatly extended our knowledge of that peculiar and extinct type of human being now known as Neanderthal man. The bones of the foot, leg, and thigh all show certain features which manifest a closer resemblance to the corresponding parts of the gorilla than do the same bones in modern man. The head was set on the neck in a manner which clearly represents a modification of the anthropoidal fixation. The earliest trace of Neanderthal man so far discovered is the Heidelberg or Mauer mandible, which was found in 1907 by the late Professor Otto Schoetensack in a stratum belonging to the older deposits of the glacial or Pleistocene period. The Heidelberg mandible clearly belongs to a very primitive type of Neanderthal man; the more humanized type became extinct long before the close of the Pleistocene period, and apparently long after men of the modern type had come into existence. There thus persisted into the Pleistocene period a race or species of man in which the body was less perfectly adapted for holding the head and body erect than is the case with modern man. Yet in the Pittdown type of *Pithecanthropus*, the head, in a geological sense, was the contemporary of *Pithecanthropus*, the conformation of his mastoid process and the muscular impressions of his occipital bone leave us in no doubt as regards this matter.

Thus in recent geological periods there have been race types of mankind showing degrees in their adaptation to posture and gait of modern man.

A survey, then, of our present knowledge of extinct forms of man permits us to make only a guarded statement regarding the date and manner of the evolution of our posture and gait. It is apparent that the adaptations which permit the head to be balanced on the neck are comparatively acquisitions; they appear to have been evolved since commencement of the Pleistocene period. The lower limb assumed a human form at a much earlier date. *Pithecanthropus* had a fully evolved human femur, and we may infer that the foot was equally human. If I am right regarding *Pithecanthropus* as representative of mankind the beginning rather than at the end of the Pliocene, then in the strata of an older period, at least the Miocene, perhaps the Oligocene, that we must look for those ancestral forms which will show us the anthropoid foot and leg assuming the characters which we regard as human. "We are far," said Darwin, "from knowing how long it was since man first diverged from the Catarrhine stock, but it may have occurred at an epoch as remote as the Eocene period." We see, then, that Darwin was prepared to find fossil remains showing changes in the foot and leg such as I have just mentioned even earlier formations than the Oligocene.

#### EVIDENCE FROM THE ANATOMY OF ANTHROPOIDS.

Having thus surveyed the evidence afforded by the fossil remains of man I propose now to inquire how far our present knowledge of the structure and habits of man's nearest allies—the anthropoid apes—will assist us in solving the problem of human posture. Our knowledge of these allies, both living and extinct, has greatly extended since Lamarck and Darwin formulated their theories, and we realize that both of these great men grossly underestimated the complexity of the problem and failed to realize that the structural adaptations which made plantigrade progression possible for man were not sudden transformations produced for man's particular benefit, but had come into existence during the evolution of the anthropoid body. It is in the evolution of the early anthropoids that we have to seek for the rise and development of the chief postural modifications of man's body. This truth was brought home to me very forcibly over thirty years ago when, as a medical officer and naturalist attached to a mining company exploring the mineral wealth of the Malay Peninsula and of Siam, I was drawn into a study of the apes and monkeys living in the jungles of these countries. These were regions in which malaria was endemic, and I set out to ascertain if the apes of the jungle suffered as much from fever as did the people of the villages. There were in my neighbourhood wandering troops of three kinds of ape, all of about the same size—weighing from 15 to 20 lb.: (1) the gibbon, the smallest and by far the most primitive of anthropoid apes; (2) various species of *Semnopithecus*, best known by their Indian cousin—the langur or holy monkey; (3) various species of the macaque monkey. My attention was soon transferred from the primary object of my investigation to the remarkable anatomical features of the gibbon's spine and trunk; in their arrangement the bones and muscles of the gibbon were altogether human, while the same parts in the *Semnopithecus* and macaque, which outwardly looked as if they might be cousins to the gibbon, were altogether different. It was then I realized that the history of many of man's postural adaptations had to be traced back to the evolution of the gibbonish or hylobatid body (*Hylobates* is the generic name for the gibbons). Nor was there any difficulty in ascertaining that these structural features of the gibbon's body were postural adaptations. In his flight from tree to tree the gibbon's manner of progression differs altogether from that of monkeys. It is true that before starting their flight the resting posture of gibbon and monkey is much the same; both sit in a semi-erect posture, resting on their ischial callosities. In progression the gibbon uses his long arms as the chief means of support and of propulsion; he leaps with his arms; the lower limbs are deftly used as accessory means of support or as the chief means when running along horizontal branches. The body is held, in all movements, upright to the plane of progression. The gibbon is *orthograde* in its gait, whereas his neighbours, the monkeys, are *pronograde*; as they passed from branch to branch, or from tree to tree, their bodies are held parallel to the plane of motion. The *Semnopithecus* was a heavy jumper; in a forward leap the impetus came from the hinder limbs and loins; the hands and arms were used to clutch the branch on

which he lighted, but were never lifted in the hand-over-hand method which is habitual in the gibbon—a true trapeze athlete. These early observations convinced me that if we are to seek for the beginnings of human posture we must first unravel the history of the gibbons.

#### *The Evidence Afforded by Gibbons.*

In point of structure the gibbon occupies a central position among the higher form of primates. It is linked to the three surviving great anthropoid apes—the gorilla, chimpanzee, and orang; all of these show a greater degree of adaptation than the gibbon to the orthograde posture. We have also good reason for believing that they are later in date of evolution. The gibbon, when allowance is made for its postural modifications, stands out as the cousin of old-world monkeys; all of these are pronograde in their gait, but in some the arms are used and developed to a much greater degree than in others; this is particularly true of those forms in which the tail has become reduced in length and strength. We shall see that the development of the tail depends on posture and gait. The gibbon is also cousin to the higher forms of South American monkeys; in some points of structure it is more nearly allied to them than to the monkeys of Asia and of Africa. The higher new world apes, although essentially pronograde in their gait, show a specialization of their hinder limbs, and in many cases a peculiar use of their tails, in grasping and climbing. While in the evolution of the gibbon the upper limbs have been exploited as means of support and progression, the specialization of function in South American monkeys has been concentrated on the lower limbs—they are used for suspension rather than for support. The structural similarity which unites gibbons, old-world monkeys, and new-world monkeys is such that we must regard all three as arising from a common ancestral form, from which has arisen a series of postural types represented in the small anthropoids and monkeys of the old and of the new world. The chief problem in the evolution of the gibbon, as of man, is the discovery of the machinery which Nature employs to mould structural form to postural function; the nature of this machinery we shall consider later. Meantime, so far as concerns the group of primates to which man belongs we may safely say that the greatest structural revolution which marks the history of this group occurred with the evolution of the gibbon. It is to this ancient structural revolution that man owes the chief of his postural modifications.

#### THE ANTIQUITY OF THE ORTHOGRADE POSTURE.

All the evidence at our disposal points to an ancient origin for the small anthropoids of the hylobatian or gibbon type. Fossil remains of them have been found in the Pliocene and Miocene deposits of Europe, and so like are they to the corresponding parts of modern gibbons that we feel certain that in the living gibbon we are dealing with an ancient and conservative type which has come through long geological epochs almost unchanged. It is highly probable that the orthograde gibbon and its pronograde cousins of the old and new worlds began to be differentiated towards the end of the Eocene period. In the Eocene formations of North America and of Europe are found fossil remains of numerous primates, but all of those so far discovered are tarsoid in form—more generalized in structure than gibbons or monkeys. The common stock from which gibbon and monkey arose will probably prove to be an Eocene tarsoid. That the orthograde hylobatian type had been differentiated from the ancestral pronograde monkey type at an early period is proved by the discovery of the remains of fossil apes in the Oligocene deposits of Egypt, which in point of geological age are intermediate to the older Eocene and more recent Miocene formations. Amongst these Egyptian fossil remains, which were described by Professor Schlosser in 1910, was the left half of a mandible of a small and primitive form of gibbon. Whether or not this early gibbon possessed the orthograde posture we have as yet no certain means of telling; but there is good reason for presuming that it did.

#### THE TROGLODYTE OR GREAT ANTHROPOID STAGE.

The first or hylobatian stage in the evolution of man's posture came during a remote geological epoch, with the appearance of the small type of anthropoid ape now represented by the gibbon. The second stage came with the evolution of the great anthropoid apes; and because the chimpanzee is the most generalized surviving member of this group and in former times was given the generic name of

Troglodytes, this stage in the evolution of man's posture may be named the "Troglodytian." All available evidence points to the great anthropoids as having been evolved from a small anthropoid ancestry. In bulk and strength of body man and the chimpanzee are nearly alike, but the male orang, and particularly the male gorilla, outstrip the strongest man in strength and weight of body. With the evolution of the great anthropoids from the small, the weight of the body undergoing then an eight- or twelve-fold increase, adaptations for the orthograde posture and gait were necessarily modified as well as strengthened. In none of the great anthropoids do the arms reach the high degree of specialization in structure and function to be seen in modern gibbons; none of them are pure brachiators as are gibbons. In the orangs, it is true, the arms are much more important and more developed than the legs for arboreal progression; in the gorilla the opposite has happened; the lower limbs are the more specialized. The chimpanzee holds an intermediate position, both limbs being developed to an equal degree, as was probably the case in early anthropoid forms. One other point deserves mention; in the gibbon, as in old-world monkeys, there are ischial callosities to serve as natural rests in the sitting posture; in the great anthropoids these callosities have disappeared. As in man, true rest is obtained by the great anthropoids only when the body is laid prone upon bed or tree scaffold.

Such scanty evidence as we now possess leads us to believe that the troglodytian, or second, phase in the evolution of man's posture, took place about the end of the Oligocene period or the beginning of the Miocene. We know of the fossil remains of at least six species of *Dryopithecus*, an anthropoid which was neither less nor more primitive than any of the surviving giant anthropoids. The earliest traces of *Dryopithecus* come from deposits belonging to the middle of the Miocene period; it will probably be found that the great or giant form of anthropoid is pre-Miocene in date of origin.

#### THE THIRD OR PLANTIGRADE PHASE.

We come now to the third phase in the evolution of man's posture—the plantigrade stage. The first, or hylobatian, stage came with the appearance of the gibbons; the second, or troglodytian, with the evolution of the great anthropoids; and the third, the really human stage with which we are now dealing, when the line leading on to man branched off from the great anthropoid stock. The structural changes which occurred in the third stage were confined almost entirely to the lower limbs. The knees and thighs became more extended and strengthened until the lower limbs came to appear as if they were a downward continuation of the trunk. The pelvis or iliacum of the lower limbs, as also of the spinal column, was modified; the hip and knee joints became adapted to the new posture; the muscles and bones of the leg assumed a human form; and, above all, the foot was transformed. We shall see, however, that underneath all that is so peculiarly human in our lower limbs there still lurk numerous vestiges and arrangements which we can only explain by supposing that at one time all the parts had passed through a troglodytian stage in their evolution. In the third stage only minor alterations occurred in the structure of the trunk. The chief adaptations to fit the thorax and the abdomen to the erect posture had been nearly perfected before the third or plantigrade stage had commenced.

In which geological period the third stage was entered and the plantigrade posture evolved we cannot as yet fix with any degree of certainty. No fossil form has yet been found in which the lower limbs are in process of transformation. It is true that the lower limbs of Neanderthal man show minor anthropoid traits, but it is also true that the femur of *Pithecanthropus* is a fully developed human form. No one who accepts evolution as a working hypothesis will have any difficulty in regarding the three great anthropoids—the gorilla, the chimpanzee, and the orang—as divergent branches from the common giant stem. Seeing that man shares so many characters in common with these we are compelled, I think, to regard man as an aberrant branch from the troglodytian stock or stem, and it is therefore probable that the plantigrade posture was evolved as soon as the common giant stock began to break up into its various living and fossil forms. We know for certain that this stock was in existence before the middle of the Miocene period; and it is therefore prior to that very remote date, most likely about the beginning of the Miocene or end of the Oligocene—two or three millions of years ago at the lowest estimate—that the plantigrade posture began to be evolved.

## THE PROBLEM OF ARTERIO-SCLEROSIS.

As Sir Clifford Allbutt<sup>4</sup> has often insisted, arterio-sclerosis is not a disease. The word should only be used in a pathological sense to define a lesion which is common to many diseases. There are three distinct aspects of the problem—namely, the description of the vascular lesion, the relative importance in the production of this lesion of various pathological and physiological processes, and lastly its causation. There is fair measure of agreement as to the description of the lesion; there is, however, no accepted opinion as to the nature of the processes concerned in its production, and its causation is largely hypothetical.

## CLASSIFICATION OF ARTERIO-SCLEROSIS.

Arterio-sclerosis is too large a subject to be considered as a whole in detail. It is conveniently divided into four main types based on anatomical changes—namely, nodular, diffuse hyperplastic, senile, and Mönckeberg's sclerosis.<sup>5</sup> This is Councilman's classification<sup>6</sup> with the addition of Mönckeberg's sclerosis. The classification of arterio-sclerosis is fully discussed by Sir Frederick Andrewes,<sup>7</sup> but I have not followed his classification, since several forms of arterial disease, such as syphilitic mesoarteritis and arteries undergoing involution, which he includes under the term "arterio-sclerosis," are excluded by definition from this review.

At the same time the four main forms of arterio-sclerosis mentioned do not include all varieties of arterio-sclerosis commonly met with. There are among others more or less mixed forms that must be placed in the class to which the more prominent lesions belong, and there are forms of diffuse intimal thickening, particularly in the aorta and larger vessels, which are fibrotic rather than hyperplastic, and which seem to undergo fatty degeneration at an early stage in their evolution. For the present I am chiefly concerned with the type of arterio-sclerosis termed "diffuse hyperplastic sclerosis,"<sup>8,9,10,11</sup> and its relation to the other three types of arterio-sclerosis will be considered later.

## DIFFUSE HYPERPLASTIC SCLEROSIS.

This type of arterial disease is the same as that termed "diffuse arterio-sclerosis" by Osler, "secondary arterio-sclerosis" by Thoma,<sup>12</sup> and "arterio-capillary fibrosis" by Gull and Sutton.<sup>10</sup> It is found in children<sup>13</sup> with renal disease and in adults with chronic nephritis (chronic parenchymatous nephritis) and true chronic interstitial nephritis,<sup>14</sup> also (as will be discussed later) in association with left ventricle hypertrophy and raised blood pressure, and lastly, in certain cases as an incident when death has resulted from some other not related cause. My observations on the histology of the lesion are based on the opinion that the nature of the arterial lesion and its evolution is the same in these different conditions and diseases, excepting that in the case of chronic nephritis it may be limited in its distribution and may indeed exceptionally be limited to the kidneys. The histology of diffuse hyperplastic sclerosis was the subject of controversy between Johnson and Gull, but Jores has made the greatest contribution to our knowledge of the lesion.<sup>15</sup> Aschoff and Gaskell<sup>16</sup> have followed up his work, and I have used the latter's method of gelatin imbedding in all my material for microscopic examination.<sup>17</sup> A short résumé of the main features of the lesion as previously described in detail<sup>18</sup> will now be given, with the addition of the description of the earliest stage of the lesion which I have not previously published.

*The Histology of Diffuse Hyperplastic Sclerosis.*

The essential lesion is a thickening of the intima in the smaller and smallest arteries. This observation is in complete agreement with Jores, and there can no longer be doubt on the matter. Reference will be made later to some observations on the histology and physiology of capillaries, and it will perhaps be shown in the future with more perfect histological technique that the earliest and most important changes are in the capillary endothelium. The intimal thickening is very uniform in the circumference of the vessel, and it may be so great as completely to occlude the lumen in the terminal arterioles, while the lumen of the parent arteries is often greatly reduced. In serial sections of kidney tissue the intimal change is fairly uniform in the length of the vessel both as regards the terminal arterioles and their parent vessels. There is no fatty degeneration in the small arteries, whereas in the arterioles there is marked fatty degeneration of the swollen intima. In a cross-section of the arteriole stained with Sudan 3 the lumen may appear completely

filled with a plug of fat, or lying a little eccentrically may be seen a rosette of nuclei, the remnant of degenerated endothelial cells.

All vessels in a single organ are by no means equally affected. In slight or early cases the affection is limited to occasional vessels. When only occasional arterioles are affected, even when the lesion is complete and the arteriole lumen appears to be completely occluded with a plug of fat, the term "diffuse hyperplastic sclerosis" is not of course applied to the condition. For example, in the case of an apparently healthy young man, aged 19, who was killed by accident, I found two arterioles in the spleen in this condition; the rest of his cardio-vasculo-renal system was perfectly normal. The lesion is regarded as one of diffuse hyperplastic sclerosis when both arterioles and their parent vessels are affected, and as a rule it is found that the lesion in the parent vessels is more uniform, though it varies in degree, than in the terminal vessels. The changes found in capillaries will be considered later in discussing nephritis; their walls undergo hyaline swelling and focal fatty degeneration, the lumen becomes occluded, and they become empty of blood.

The intimal lesion in diffuse hyperplastic sclerosis is the structural change by which this form of arterio-sclerosis is recognized. Its chief incidence is on the finer ramifications of the vascular system, the terminal arteries and their parent vessels being chiefly or only affected; when the arteries from which the so-called parent arteries are given off are affected, they show similar changes to those seen in the parent arteries, while the intima of vessels of the size of the renal and radial artery is fairly normal in appearance. I have not identified a characteristic change in the larger vessels such as the aorta and its branches apart from the medial hypertrophy which is apparently present in marked cases of diffuse hyperplastic sclerosis associated with a raised blood pressure and left ventricle hypertrophy. In some cases the larger arteries show structural changes characteristic of nodular or senile arterio-sclerosis.

The distribution of the lesion in the several organs of the body shows considerable uniformity. The kidney and spleen are most commonly affected; so far as I have observed the spleen is not affected independently of the kidney, but since there are occasional cases in which the kidney is affected without the spleen being involved, it follows that of the two organs the kidney is rather more often affected than the spleen. The incidence of the lesion in the splenic vessels is a criterion of its general incidence in other organs, the kidney affection being a less reliable criterion because of the association of the vascular lesion with chronic nephritis. The brain appears, from my observations, to be the next organ most liable to this vascular lesion; and after this come the pancreas, liver, suprarenal glands, and, less often, the vessels of the stomach and intestines. I have seen no specimen in which the lesion was present in the heart; 70 cases have been examined, including many in which the lesion was well developed in other organs, hence it follows that its presence in the heart vasculature must be uncommon. The lesion has not been found in skeletal muscle. Other organs have been examined, and the lesion has been found in lymphatic glands and in one case in the ovaries; no example of the lesion has been found in skin, pituitary, thymus, urinary bladder, prostate, or uterus, but too few specimens have been examined to lend weight to the absence of the lesion in these organs.

*Nature of the Intimal Thickening.*

The sequence of changes that take place in the thickening of the intima cannot be determined by the investigation of the condition of the vessels in a single subject, and it is of course an assumption to describe as occurring in a sequence the various changes observed in different vessels in organs taken from different subjects; at the same time I believe that the changes in the arterial wall occur in the order that I now intend to describe. The first change to occur in the arterioles is a swelling and proliferation of the endothelial cells (Fig. 1). The new endothelial cells become flattened and undergo hyaline swelling, and the next stage in the process is the appearance of fatty granules in the cells (Fig. 2). The stainable fat increases, the granules coalesce, the cell outline is lost, and finally the cell protoplasm is replaced by fat. It is at this stage that the arteriole is frequently seen in cross-section with its lumen plugged with fat and the nuclei forming a tiny rosette in the centre. Ultimately the nuclei disintegrate and disappear, and the last cells to survive are those

nearest to the lumen, perhaps because they are the youngest, most recently formed cells, and because of their situation have the best supply of oxygen. In serial sections of arterioles parts that have undergone hyaline swelling merge insensibly into areas, or rather lengths of fatty degeneration; there is also a variation in the amount of Sudan 3 taken up, and its colour varies between yellow and vermillion red. When the arteriole is traced into the vessel from which it springs the fatty degeneration is seen to stop short at the wall of the parent vessel. This vessel characteristically contains no fat within its walls, and is in this in striking contrast to the fatty degeneration in the terminal arteriole.

#### *Changes in the Parent Vessels.*

The thickened intima of the parent vessels—a thickening which may be so marked as nearly to obliterate the lumen—consists of cells, fibrils of connective tissue and elastic tissue, and hyaline intercellular substance. The prominent feature of the thickened intima is the amount of hyaline substance present, the new formation of connective tissue, and the fine fibrils of elastic tissue that permeate the whole coat. In active and early lesions there is a considerable increase in the number of cells present, but more often there is a relative paucity of cells, though allowing for the great increase in the thickness of the intima there is even in these cases an increase in the number of cells over those present in the normal intima.

1. *Cellular Proliferation.*—Endothelial proliferation is more difficult to demonstrate in the parent vessels than in the arterioles, but there is no doubt of its occurrence. Fig. 3 shows an active stage of endothelial proliferation in a vessel taken from a section of a kidney with chronic nephritis. Fig. 5 shows a later stage, an appearance more frequently seen; the inner layers of cells are flattened endothelial cells, and they are seen lining the lumen in a close-up view of the same artery shown in Fig. 6. It is probable that some of the cells in the thickened intima arise by proliferation of the subendothelial cells.

2. *Origin of Elastic Fibres.*—Elastic fibrils are laid down by cells morphologically identical with connective tissue cells,<sup>22</sup> and in addition to this method of formation it has been suggested by Jores that the elastic tissue of the hyperplastic layer arises by a process of growth and splitting of the internal elastic lamina. The appearance of some sections of diseased arteries suggests the possibility of elastic fibrils being laid down directly by endothelial cells. In a case of endarteritis obliterans (type of Winiwarter) affecting the anterior tibial artery there was great thickening of the intima arising suddenly, almost like a shelf, in the lumen of the vessel. The thickened intima was enormously cellular and the cells had the appearance of flattened endothelial cells, in between which were found fibrils of elastic tissue almost enfolding the cells in their meshes. At one place the endothelial cells were arranged in a number of concentric layers enclosing a lumen, and near the lumen of this vessel, which seemed to be in the process of formation *in situ*, was a thick folded layer of elastic tissue, and lying flat on it, almost like slugs on celery, were endothelial cells.

3. *Origin of Hyaline Substance.*—The formation of hyaline is not without doubt a degenerative process. Adams<sup>19</sup> uses the word "inflammation" as reaction following injury, and the response to it. For the sake of clearness for my present purpose I would add the words "and to the effects of it." In distinction from a process of inflammation a process of degeneration is one in which there is no reaction on the part of the affected tissues to the change in their environment, the changes observed being a passive result of the alteration in environment, and the later phases of these changes are loss of function and cell death. I apply the term "degeneration" when fat appears in cells that do not normally contain it. Thus if an intimal cell contains fat it is regarded as undergoing the process of degeneration, whereas, of course, the appearance of fat in a liver cell has no such significance. It is agreed that the appearance of amyloid and calcification is evidence of degeneration. It is with the interpretation of the earlier phases of the process of degeneration that the difficulties occur. Thus it seems that cloudy swelling and a hyaline change may be either inflammatory in the sense that I have defined the word (that is, in its widest sense) or degenerative. Hyaline change is indeed commonly classed among the processes of degeneration in textbooks of pathology, and is in fact referred to as hyaline degeneration. In many instances the origin of the hyaline

material is difficult to determine, in other cases there is little doubt as to its origin. Thus masses of hyaline deposit may become hyaline, as may blood coagula in thrombi of aneurysms, and similarly the thrombi of a vessel may undergo hyaline change. The hyaline change occurring under these circumstances is regarded as a degenerative change, and the clearest example is the material of dead protoplasm washed with tissue fluids to hyaline material.<sup>23</sup> Hyaline material appears also to be derived directly from cells, either as a secretion by glandular epithelium or as an accumulation of hyaline substances in the protoplasm of the cells. It is probable that the hyaline in the intima of the thickened arteries now under discussion arises in this way by a process of secretion by the endothelial cells or by the subendothelial cells. The coincident appearance of hyaline substance and cellular proliferation, the fact that the change does not progress to fatty degeneration, and lastly, the clear outline of the cells in the thickened intima and the good staining of their nuclei, are reasons for refusing to accept the presence of hyaline substance as evidence of a degenerative change. This point of view is clearly stated by J. Lorrain Smith, who writes:

"Hyaline material is deposited in the walls of capillaries causing a gradual leading to closure of the lumen. The appearance of the endothelial cells. This change is seen in senile conditions, and also in chronic inflammation, where it extends beyond the vessel newly formed connective-tissue fibrils. In these examples it originates chiefly in the endothelium and may be regarded as secretory in form."

4. *Origin of Connective Tissues.*—The question of a degenerative process being involved in the formation of the fine connective tissue fibrils that permeate the thickened intima in diffuse hyperplastic sclerosis does not arise. There is no doubt that the process involved is one of inflammation in the sense in which that word has already been defined; in fact, the definition need not be so wide, and the word in this connexion can be used in the limited sense of "reaction following injury and the response to it." As has already been seen there is no necessity for regarding the hyaline substance as a degenerative change, and therefore there is no need to explain the formation of connective tissue as an effect of the presence of hyaline substance. It is generally held that the connective tissue which often forms an appreciable part of the intimal thickening is derived from the subendothelial cells which by their proliferation contribute to the cell increase in the thickened intima. In addition to its origin from these cells it is possible that some of the connective tissue is derived from the endothelium. Thus Baumgarten has made observations which indicate the origin of fibroblasts and connective tissue from vascular endothelium under mild grades of irritation. Sir Bernard Spilsbury allows me to quote his observation of the appearance of connective tissue fibrils immediately under the growing layer of endothelial cells as they spread over a newly formed thrombus on a heart valve; in this latter case there were no cells in the neighbourhood from which the connective tissue could have been derived other than the endothelium.

#### *Summary and Discussion of Changes in Intima, Media, and Adventitia.*

Joseph Coats<sup>21</sup> maintained that the essential constituent of blood vessels is the intima. The endothelium is the universal lining of the vascular system; every vessel, in fact, has an intima, but only the arteries and veins have a media and adventitia; also in the formation of new vessels the primary event is the formation of a tube composed of endothelium by a process of budding from existing vessels. The paramount importance of the intima in health is maintained in disease, and I believe that the endothelial changes are the key to the interpretation of the lesion in diffuse hyperplastic sclerosis. It may be possible in the future to be more explicit in this statement and to bring forward convincing evidence that the endothelium plays the greater part in the intimal change. The specimens have been shown in which there is active proliferation of the endothelium; evidence has been brought forward that raises the question of elastic tissue formation by endothelium; the formation of hyaline material by a process of secretion from endothelium has been discussed; and finally, the formation of connective tissue by endothelial cells may be accepted as a fact. In short, the various constituents of the thickened intima in diffuse hyperplastic sclerosis, the proliferation of cells; the increase of elastic tissue, the formation of connective tissue, and the production of hyaline substance

FIG. 1.—A terminal arteriole showing proliferation and swelling of endothelial cells; the lumen is almost obliterated and is occupied by a mononuclear cell. The earliest stage of diffuse hyperplastic sclerosis.

FIG. 2.—A later stage of the lesion, showing an arteriole with having undergone transformation (shown in section 3), with shows a still later stage, in which the lumen is completely obliterated and the cells further degenerated. The media is intact in each arteriole.

FIG. 4.—Same vessel as Fig. 3, stained with Weigert's elastic stain to show new formation of elastic tissue.

FIG. 5.—A later stage of the same process. The endothelial cells are now flattened; the new-formed elastic tissue is more regularly disposed.

FIG. 3.—Endothelial proliferation in a parent vessel with simultaneous formation of elastic tissue. No fatty degeneration present. Early stage of lesion.

FIG. 6.—Close-up view of part of wall of same vessel to show the flattened endothelial cells, the new-formed elastic layers, the internal elastic lamina, the media, and surrounding kidney tissue in this order from above downwards.

FIG. 10.—Push-plough method. Final stage.

may all result from the increased activity of the endothelium. It will be remembered that in pure forms of diffuse hyperplastic sclerosis—and in speaking of "pure" forms of diffuse hyperplastic sclerosis I mean to exclude those cases in which senile arterio-sclerosis complicates the picture—fatty degeneration is confined to the terminal arterioles of the kidney and the smaller vessels in other organs. The presence of fatty change in these vessels will be referred to later, but the point that I would make now is the absence of any change that is beyond doubt degenerative in the vessels of second size—that is, the parent vessels of those affected by fatty change.

In addition to the thickening of the intima there is sometimes hypertrophy of the media in diffuse hyperplastic sclerosis. This is the only change in the middle coat, pathological changes being characteristically absent. The medial hypertrophy cannot otherwise be regarded than as a physiological response to the increased blood pressure that is present in the majority of cases of diffuse hyperplastic sclerosis. I have previously called attention to the fact that diffuse hyperplastic sclerosis of limited extent may be found after death in bodies in which the heart is not increased above 15 oz. in weight, and in which the blood pressure during life was below 180 mm. Hg. Hypertrophy of the media is not evident in these cases. There are also cases of diffuse hyperplastic sclerosis in older cases in which fatty degeneration of the media occurs and the media appears stretched in section and apparently thinner than expected in a normal artery of the same size. I have not made exact comparison in these cases, and can only express the opinion from my observations that medial hypertrophy is a common accompaniment of marked cases of diffuse hyperplastic sclerosis, and that it is present in cases in which there was a definitely raised blood pressure during life or marked hypertrophy of the left ventricle after death, though there are slighter cases of diffuse hyperplastic sclerosis in which no medial hypertrophy occurs. This medial hypertrophy is neither the essential element nor a constant feature of diffuse hyperplastic sclerosis. It is possible that the raised blood pressure precedes the vascular lesion in some cases, and it may be, therefore, that medial hypertrophy precedes intimal thickening under these conditions; in any case the medial hypertrophy is frequently so pronounced that it is regarded by some observers as the essential element in this form of arterio-sclerosis.<sup>12</sup>

Gull and Sutton emphasized the thickening of the adventitia in arterio-capillary fibrosis. This is present in some cases, and I have noticed it in the renal vessels and perhaps also in the spleen. It is difficult to distinguish between an increase in the adventitia and an increase in the perivascular connective tissue which is present in considerable quantity in both these organs. It has escaped my observation in other organs of the body, and needs closer study than I have given it.

#### Conclusion.

The main feature of diffuse hyperplastic sclerosis is a thickening of the intima, accompanied sometimes by hypertrophy of the media. The intimal changes are the essential lesion. Activity of the endothelial cells is largely responsible for the intimal thickening. In this thickening the process of degeneration plays a secondary part; it is only certainly present in the terminal arterioles of the kidney and the smallest vessels of the other organs. The characteristic feature of the lesion is an intense tissue activity, which is the very antithesis of a process of decay. The nature of the process concerned in the production of this lesion will be considered in the next lecture.

## An Address

ON

## TREPHINATION OF THE LIVING HUMAN SKULL IN PREHISTORIC TIMES.\*

BY

T. WILSON PARRY, M.A., M.D. CANTAB., F.S.A.

[With Special Plates.]

SIXTY years ago not even the most eminent scientist in Europe was aware of the fact that, in prehistoric times, our primitive ancestors used to trephine the living skulls of their fellow tribesmen with implements made of stone. The knowledge of this was rendered possible by a discovery made by a general medical practitioner. And here I should like to say that such of you as are about to enter general practice will find, I think, this branch of our profession of a peculiarly satisfying nature, in that not only does it have for its aim the carrying out of ethical ideals by sound practical methods, but there is scope, at leisure moments, for the study of those wider interests that do not actually belong to our profession, but which are stimulated by the atmosphere created by our education, trend of thought, and environment.

Prunières, a general practitioner of Marvejols in the department of La Lozère, France, was a man who spent much of his spare time in antiquarian research. While examining a large dolmen, near Aiguères, in 1865, he discovered a skull with a curious hole in it. The hole had smooth, shelving edges which looked as if they had been polished. Prunières was puzzled as to the nature of this hole and came to the conclusion that, finding the skull in a dolmen, it had belonged to a Neolithic savage and had been converted into a drinking cup, a custom which not infrequently exists among savage tribes, and that this smooth-faced hole had been specially designed for the application of the lips. Now these dolmens were constructed during the third or Carnac stage of the Neolithic period, which ended in north-western Europe about two thousand years before the Christian era. The whole of the Neolithic period is computed to have lasted some twenty thousand years, the third and last division probably occupying from four to six thousand years, so that the age of these dolmens may be estimated as being not less than four and even as much as eight to ten thousand years old—the last word in these megalithic buildings being that magnificent pile known as Stonehenge, which was erected at the beginning of the Bronze Age.

Prunières was not correct in his surmise about the drinking cup. To Broca belongs the credit of explaining that the smooth, polished-looking surface of the sides of the hole in this skull was due to a healing process that had taken place in a wound of the bone during life. After this first discovery many other specimens were unearthed from the dolmens existing in those regions, so many, indeed, as to compel one to believe that, during the latter part of the Neolithic period in France, a fetish of a most extraordinary kind was prevalent among the inhabitants, and this fetish consisted in trephining the healthy human skull for some purpose of a superstitious nature, for none of the skulls showed any sign of either fracture or disease.

And now comes the point when it might very reasonably be asked, How can you definitely prove that these holes, which we now know were made during life, were the result of an operation, deliberately planned and carried out by Neolithic man? Is not this suggestion merely guesswork? Broca, having found out all he could from the nature of the specimen itself, and from the place where it was found, and the associations, turned his eyes in another direction.

Here it may be explained that all primitive tribes, on their way upward from savagery to civilization, pass through the same phases. Every nation starts with its so-called "Stone Age," when the chief material used for the making of their implements is stone. Wood, slate, shell, bone, and teeth are also used during this period. When culture has proceeded farther, metals are discovered, the first being the more malleable ones—copper and tin. By accident or experiment they find that a harder and much more serviceable metal is obtained by blending these two metals by heat, bronze being the outcome—thus the Bronze Age. When iron is discovered a stupendous advance has been made, and the early Iron Age.

\* Given before the Listerian Society of King's College Hospital on January 17th, 1923.

of any tribe denotes that great progress has been effected by that tribe. My point in mentioning this is to demonstrate that if only we study the life and customs of those tribes who are still going through their age of stone culture we are able, by analogy, to explain what our own ancestors did when they were passing through this early stage of evolution.

Information had been brought by travellers from certain of the South Pacific islands that the natives there actually performed this operation, at that time, on their living comrades with implements made of obsidian, shell, or shark's teeth. Since the white trader had visited those islands and introduced glass bottles—unfortunately usually in the form of whisky receptacles—the natives had manufactured implements from this glass and used these in preference to those of obsidian formerly employed. Broca had heard tales of this, and he actually made an experiment on a dead infant's skull with a piece of sharp-edged glass, and found that a hole could be made quite quickly and easily by its means. Broca had, however, only been imperfectly informed, as he came to the conclusion that all these trephine holes, in the many specimens found in France, had been made when the subjects were infants. He had not been told and he did not believe that the operation was actually performed during life on adults.

#### EXPERIMENTS TO DEMONSTRATE METHODS OF PRIMITIVE TREPHINATION.

Ten years ago, in order to get a correct and practical understanding of how primitive man (Neolithic and Modern) performed this operation, I began a series of some fifty experiments on both recent and dry human skulls with all the primitive implements that have been used for the purpose—namely, flint, obsidian, shark's teeth, shell, glass, and even slate. The only material likely to have been used in north-western Europe was stone, and the kind of stone best suited for the purpose is flint. Flint is, as you are well aware, of sedimentary formation, and it possesses the power when force is brought to bear upon it in a certain way of being split into flakes. These flakes can be made, according to the skill of the knapper, with sharp points and edges, and make excellent knives, saws, scrapers, and borers, such as would be required in any primitive household. Neolithic man also constructed most exquisitely shaped arrow-heads, spear-heads, and javelin-heads, for defence of the home and offence in the hunting and fighting field.

With these crude implements at his disposal Neolithic man, in different parts of the world, conducted this somewhat hazardous operation without anaesthetics, without antiseptics, and with dressings which would have shocked the susceptibilities of any member of the Listerian Society. And yet with all these drawbacks he got, like the present-day quack, amazing successes. I make out there were four principal methods by which he performed this operation—namely: (1) by scraping the bone (Figs. 1 and 2); (2) by boring a circle of holes and sawing the intervening spaces (Figs. 3, 4, and 5); (3) by furrowing the bone by the push-plough method (Figs. 6, 7, 8, 9, 10, and (?) 11); (4) by sawing out a quadrilateral button of bone (Figs. 12 and 13).

##### 1. Scraping.

Whether the scraping be done by flint flakes, sharp-edged pieces of obsidian, or pieces of strong sharp shell, such as are found on the shores of the South Pacific islands, the principle and method of procedure are precisely the same. For scraping a hole in bone, metal not being considered, there can be no better natural implement than a well flaked piece of flint. Where flint cannot be obtained, as in volcanic regions, obsidian makes a good substitute. Obsidian is a natural volcanic glass, and can be flaked in the same way as flint by a sharp, well directed blow. The obsidian I used came from the Lipari Islands, north of Sicily. Contrasting these two substances I would give flint the first place. A hard, sharp edge can be obtained in flint, which is more resistant to counter-pressure than is obsidian. Obsidian, like glass, can give an even sharper edge than flint, but it is much more brittle and the operator stands in some danger as regards his eyes, from the sharp spicules that fly in every direction. I may recall that while flint is a siliceous sedimentary deposit, obsidian is of igneous formation; both flint and obsidian, when freshly flaked, are excellent substances for surgical purposes. Their newly fractured surfaces, which are smooth—and in this respect obsidian would take pre-eminence—are aseptic, and this is a point of great practical value of which the primitive operator stood in blissful ignorance. It surprised me at first, in no small measure, to find how cleanly and easily a flint

knife could cut through the scalp, and obsidian I found equally as good if not better. At the present day the natives of the Andaman Islands shave their heads with obsidian knives. The method I employed for scraping the trephine-hole with both flint and obsidian was the following. Having made a V- or Y-shaped incision in the scalp, as is done by the primitive Melanesians, over the selected site of the operation, I scraped as nearly as possible along a single line on the bone with a flint flake, which I held between the thumb and forefinger of my right hand. [Although Sir John Evans believed that our Neolithic ancestors used to haft some of these small flakes, I am convinced that no hafted implement was used in this case. This can be substantiated by the Melanesian method employed in these days, when the obsidian flake or piece of glass is held between the finger and thumb.] This line I gradually converted into a groove, which soon showed two more or less prominent ridges. The outer table of the skull is by no means as easy to remove in this manner as might be expected. The next step was to attack the edges of the groove with a curved movement of the scraper till a depression was produced in the bone, which gradually assumed an elliptical shape. It is now only a question of time and manipulation to convert this elliptical depression into a circular one, and thence, having penetrated the inner table of the skull, to expose the dura mater and enlarge the foramen in the bone to the size and shape required. In only one case can I remember slightly damaging the dura mater, and the reason of this was that my supply of Neolithic implements was limited and I had not to hand at the moment the particular shape I required. It must be remembered that when Neolithic man did this operation he would be bountifully supplied with probably hundreds of sharp, newly cut flakes, and immediately one became blunted, or was not to his fancy in any other way, he would naturally fling it aside and choose another. The average time taken by me to do this operation on a fresh adult skull was half an hour.

Trephining by shell was probably never attempted by Neolithic man in Europe, as our shells are not nearly strong enough to compete with such a substance as flaked flint, of which we possess a remarkable abundance. Primitive man, in the South Pacific islands, most certainly used shell for trephining, shell knives for ordinary use, and shell lancets for opening abscesses. I experimented, however, with an ordinary beach-worn oyster shell, and found I was able to trephine the skull of a 9-months-old infant in about twenty-five minutes, and, to my amazement, with a larger and stronger shell I made a large hole in the somewhat soft skull of a Maori in thirteen and a half minutes. What could not, therefore, be done with some of the powerful shells that are so prevalent among the islands of the South Pacific Ocean?

##### 2. Boring with Sawing.

Whether hand flint borers (Fig. 3), hafted flint borers, flint-tipped mechanical borers (Fig. 4), or hafted shark's teeth be used, the method employed is precisely the same. A series of holes, packed as closely together as possible, were bored in the form of a circle. These would number perhaps from fifteen to twenty-two, according to the size of the bone required to be removed. Having done this the bridges of bone between the holes would be cut through either by the side-to-side action of a strong flint flake or by means of a flint saw (Fig. 5). The enclosed rondel of bone was then liberated. This is a very arduous operation, especially if the holes are made by a hand borer (Fig. 3). A hand borer is a flint implement tapering to a point, held either directly in the hand or hafted into a wooden handle and used as if it were a clumsy bradawl. A quicker and much more effective method of drilling holes was most probably used. The bow drill (Fig. 4) is one of the oldest mechanical contrivances in existence. Canadian Indians, in pre-Columbian days, used one of these, without having any hard material affixed to its end, to make fire by friction against another piece of wood, touchwood or dried leaves being placed in near proximity to catch the spark. With a sharp point of some hard material this contrivance was used for drilling holes. I show you a lantern slide of an Incan skull on which this operation has been performed. I think the regularity of the holes and their proximity to each other will convince you, as it has convinced me, that they have been bored by mechanical means. This operation takes a considerably longer time to perform than one done by scraping, but, of course, a much larger hole can be made. It took me twenty-five minutes to do the first stage alone (drilling the circle of holes) on the cadaver of a male 68 years

of age, and it took me sixty-five minutes to remove a rondel from the skull of a female 40 years of age.

Another method of boring holes, and one which was formerly used in Melanesia, was by shark's teeth. As regards shark's teeth as surgical instruments, I am satisfied that, metal being again excluded, there is no more excellent natural implement for boring holes in bone than a hafted shark's tooth. Its keenly serrated edges and its strong, sharp point make it an instrument invaluable to the primitive surgeon. It moreover possesses a natural flange, which converts it into a trephine of undeniable utility, for the flange is so placed as to prevent the point penetrating too deeply into the thickness of the bone to the wounding of the dura mater. A ring of holes, packed closely together as before, followed by the breaking down of the bridges between them by a scraping and saw-like action of the implement, makes a hole, after removal of the rondel, with which any surgeon may be happily satisfied. Although it took me only twelve minutes to do this operation on the skull of an infant aged 14 months, it took me one and a quarter hours to do the first stage only of the same operation on an adult dry specimen and one and three-quarter hours to do a complete operation on another dry specimen.

### 3. The Push-plough Method.

Coming under neither of the two previous heads (scraping or boring) is, I am convinced, another primitive surgical procedure to which I find no reference in the literature of the subject. Lucas-Championnière does not successfully tackle the problem of how those skulls, found in the French dolmens, exhibiting extremely large trephinations, were

operated upon to produce such extraordinary effects. As the edge of the trephine ring shows a partial healing process they cannot be classed as examples of *post-mortem* mutilations of the skull for the purpose of making amulets. In the Museum of the Royal College of Surgeons casts of some of these skulls can be seen, and it fills one with amazement to consider the daring of the primitive surgeon, a feeling which, unfortunately, is mingled with a lack of admiration for his

Fig. 11.—The "Edinburgh" prehistoric (?) trephined skull. (Wellcome Hist. Med. Museum.)

quality of judgement. Lucas-Championnière was inclined to believe that those trephinations that were not done by scraping were done by boring and sawing in the way we have already described. Now no one could possibly imagine that these large trephinations of which I speak were done merely by scraping the bone with a flint scraper; they are much too large for that, consequently it is inferred they were done by the boring method.

It is inconceivable to me that a large boring operation could be performed without there being left behind indisputable evidence of this method having been employed, for when the bridges of bone separating the perforations are cut through a large very ragged ring, comprised of half-holes and half-bridges, remains to tell the tale of how the rondel had been removed. No amount of new bone formation could completely obliterate this. It is possible, I grant, that by extending an already abnormally long operation the surgeon, by a special scraping manipulation, could have done this. But was this likely? In a carefully planned burglary the expert thief thoughtfully leaves behind no trace of his criminal work whereby he may be identified. The Neolithic surgeon was not placed in this position. An operation of this kind would take some hours' hard work, and even if the patient had not become weary of it the surgeon himself would begin to show signs of fatigue and would not be anxious to prolong the proceeding merely for aesthetic reasons.

In the Geological Section of the Museum of Lisbon is a cranium that was taken from the grotto of Casa da Moura at Peniche in Portugal. This grotto contained the remains of no less than 140 individuals of the Neolithic period. This cranium exhibits an unfinished trephination on the left parietal bone, the piece to have been removed being elliptical in shape, 60 mm. long by 20 mm. broad. There are no signs of reparation, which means either that the patient died before the operation was completed or the surgeon gave up either for his own or the patient's sake. I think we may

perhaps best describe it as the first stage of another kind of operation. To me it furnishes a valuable clue as to the nature of the finished operation, which would when completed have represented, in my opinion, the method employed by the "French" Neolithic surgeon to bring about those large trephinations of which I have spoken. I think this operation was done by pushing forward a beaked flint implement, used in such a way as to first make a line, then a shallow groove, then a furrow, which, when deepened by continually traversing the same direction, eventually would plough through the diploë and reach the inner table of the skull. When nothing but the vitreous layer remained the rondel would be levered out by a stone or bone elevator (Figs. 8, 9, and 10). Professor Sir Arthur Keith, Conservator of the Museum of the Royal College of Surgeons, agrees with me that this was probably the method employed in removing the great pieces of skull bone which specimens prove were actually accomplished—unhappily, alas! not to the benefit of the patient so treated.

### 4. Sawing.

There is yet another method that was made use of in prehistoric times. We have no proof, however, that this method was employed in Europe, in Africa, or in any of the islands of the Australian Archipelago.

It was a very dangerous operation, and there is not on record a single case of success. It consisted in sawing out, with a stone implement, a quadrilateral button of bone, by four straight cuts, leaving on the skull a figure closely resembling a parallelogram with extended sides, such as we were wont to draw as children when playing the game of naughts and crosses (Figs. 12 and 13). If the skull were a level plane there might have been a shadow of a chance of success; but, the skull having a contour of its own, it stands to reason that in order to penetrate the inner table of the skull equally in every direction, which was necessary for the removal of a piece of bone, that part of the skull which was most convex would have to be cut deeper

Fig. 12.—Skull of prehistoric Peruvian, discovered by Mr. E. G. Squier in 1867.

Fig. 13.—Experiment on dry skull, with flint saw, to show how the Incan skull had been trephined.

E. G. Squier (Fig. 12). Both Broca and Nélaton examined this skull, the former giving it as his opinion that the patient lived no longer than seven days after the operation, while the latter put it down as ten. This was judged, of course, by the amount of reparation exhibited by the edges of the aperture. I show you a lantern slide of this skull, as well as of two others which were also excavated in Peru.

### SHOCK AND ANAESTHETICS.

There is very little shock, I am convinced, with this operation. There is no feeling in bone; if an exposed piece of healthy bone be tapped with a probe the patient does not flinch. Moreover, the scalp has not the keen sensitiveness of other sentient surfaces in the body. I was very fortunate,

during the war, in coming across a Polish doctor from Warsaw who had been doing research work on this very subject in Germany, but had been obliged to take refuge in our country. He would not permit me to make known his name, so I very much regret I cannot give him that personal acknowledgment he deserves in this branch of research. He was working with Dr. Klaatsch of Breslau, who was professor of anthropology in Dresden. He performed operations (primitive and otherwise) on cats and dogs in connexion with trephination (occipital and frontal) to test the amount of shock occurring in connexion with them. Cats and pigs are particularly nervous subjects and show glycosuria on the least provocation of shock. Dogs and rabbits show shock or pain by intestinal contractions; thus shock can be scientifically estimated. The results of the experiments were that no glycosuria occurred from performing the primitive operation of trephination, with flint, on cats, and shock was found to be very slight with the same primitive operation performed on large dogs.

Probably the two earliest discovered anodynes were mandragora and opium, as both these drugs are mentioned in the Papyrus Ebers, which was found near Thebes, and dates from the eighteenth dynasty, about 1500 B.C., some five hundred years after the age of stone culture had closed for France and Great Britain, and indeed for the greater part of Europe. The first mention of opium in Europe is by Theophrastus, which did not occur till 300 B.C. In the first century Dioscorides describes the method of obtaining the juice from the capsules, and Pliny describes its medicinal uses. Dioscorides describes how "Cyprus wine" was made from the mandragora root, and that a dose of it was given to a patient before operating to induce sleep. Among the Swiss lake dwellings a whole cake of the seeds of the garden or opium poppy was found at Robenhausen, but as these seeds are destitute of narcotic properties, which are almost entirely confined to the capsules, the seeds were no doubt pressed for the extraction of oil, or, it has been suggested, they may have been eaten scattered on bread.

About twenty years ago an interesting custom was discovered amongst the Peruvian Indians. They fill a wound with powdered coca leaves, which contain some 9 per cent. of cocaine, and they find after waiting a little while they can do what they like with the part affected without inflicting pain. It is not unlikely that the Incan and pre-Incan races availed themselves of this local anaesthetic when they performed their trephinations, though we have no evidence that this method was used in Europe. Mr. Hilton-Simpson has lately been studying primitive surgery among the Arabs in Algeria. Trephination, which is not at all uncommon there, is always performed without an anaesthetic. He told me that he had witnessed an operation on a young girl, who, becoming restive and noisy, was only silenced into operative subjection by a terrible outpouring of oaths and foul language administered by the operating surgeon himself. I have no doubt that some such hypnotic anaesthetic was employed by the Stone Age medicine man.

#### DISTRIBUTION OF PREHISTORIC TREPHINATION.

The distribution of prehistoric trephination is almost world-wide. It is found in parts of both the eastern and western hemispheres. It must be understood, however, it was never synchronous in these different regions of the earth, thousands of years sometimes separating the practice in one part of the world from that in another. To give just one example. In this country it was practised some four thousand years ago, while in Melanesia—that group of islands situated in Oceania to the east of New Guinea and Australia—primitive trephination is performed to-day with all the simplicity and crudeness it was practised in prehistoric times thousands of years ago. There is no doubt that an ethical need for it arose at a certain time among diverse primitive civilizations when in the state of stone culture, demonology, with special reference to epilepsy, being the primary cause of its being first suggested and then practised. Although migration may have had influence upon this strange custom being disseminated, I do not believe it was answerable for its unified spread, the reason being that it was used in one part of the world for an entirely different reason from what it was in other parts. In one part of Melanesia it is actually employed to promote longevity, handsome youths and beautiful girls being specially singled out for its practice.

In the eastern hemisphere Europe has the distinction of being the leading continent, and in Europe France is the first

country, by a long way, to be able to exhibit the largest number of specimens of this unique fetish. Great Britain, Scandinavia (particularly Denmark and Sweden), Germany, Bohemia, Poland and Russia (especially the Caucasian region), Portugal, and Montenegro, have all some skulls to prove its practice in those countries. I know of none that have been yet found in Spain or Italy. Passing over the Mediterranean Sea we find it has been practised in Algeria amongst the Kabyles from very early times, and it is to-day performed by the Arab Shamans, with primitive metal instruments, in the most primitive way, without anaesthetics, without antiseptics, and with the crudest possible dressings. Specimens have been found in the Canary Isles. In Tenerife von Luschan collected 210 Guanche skulls, ten of which had been trephined. He found others in which the outer table only had been scraped away. Professor Elliot Smith has examined 15,000 skulls from ancient Egypt and Nubia, but tells me he has never found a trephined specimen. I should like to show you a lantern slide of one of them. I have not seen this skull, but the specimen seems to me to so clearly illustrate a depressed fracture that has been treated in this way that I bring before your notice two pictures of it—one a front view and the other a profile one. The Guanches are supposed to have migrated from Egypt, so one would have expected to have found specimens there. It is possible, of course, that the custom was acquired in the Canary Isles after they had been separated from the mainland of north-west Africa.

In Asia, Daghestan can exhibit primitive specimens, and they have also been found in Japan; but the vast area of Asia has hitherto been unexplored from this view-point, and one day, no doubt, other specimens will be unearthed, when new classifications will have to be made.

In the western hemisphere we find no specimen whatever to prove that this operation was attempted on the living skull in North America; but post-mortem specimens have been discovered in Michigan, Illinois, and Ohio.

In Mexico, among the ancient Tarahumares, Lumholz discovered two skulls that had been trephined in a primitive manner, one during life and the other after death.

Very many specimens have been excavated in South America, notably in Peru, where the Incan and pre-Incan races practised this art for surgical and most probably for medical and ethical purposes, though not a single human amulet has yet been discovered there. In Bolivia specimens have also been found.

The imaginary line separating the eastern from the western hemisphere cuts through the group of islands in the South Pacific known as Melanesia. In this group it was practised. There are specimens in the Museum of the Royal College of Surgeons from both New Britain (Nou Pommern)—where the operation is performed for fractures only—and New Ireland (Nou Mecklenburg)—where the operation is performed for epilepsy and insanity. In 1874 Ella described an operation that he had himself witnessed in Uvea in the Loyalty group, and as early as 1831 William Ellis described an operation that he had seen performed in the island Bora-Bora in the Society group, over 2,500 miles to the east of the Loyalties. It is still practised in many of these islands, sometimes for fractures of the skull produced by sling-stones or by clubs, and sometimes for epilepsy or other head disorders supposed to be caused by demoniacal possession.

I will finish by showing you the lantern slide of a skull mounted in an elaborate glass-sided reliquary, which is to be seen in the cathedral at Avranches in Brittany. The skull is supposed to have belonged to Saint Aubert, who became Bishop of Avranches in the year 708, founded the church on St. Michael's Mount, and died in 725. This skull has a circular hole in it which was supposed to have been made by the forefinger of the Archangel Michael. If you will examine the hole carefully you will find it is an exact replica in size, shape, and shelving edges of one of those holes I have been showing you to-night—a facsimile, indeed, of a prehistoric trephination; and I suggest to you that if it is not what it purports to be it is a Neolithic trephined skull that must have been found in one of the many dolmens that exist in Brittany, the Carnac region of which has played such an important part in European Neolithic history. The individual in question, therefore, who owned this skull must have lived some three thousand years before Saint Aubert, the learned Bishop of Avranches, was born!

## THE VALUE OF LABORATORY TESTS IN DISEASES OF THE LIVER AND PANCREAS.\*

BY

W. LANGDON BROWN, M.A., M.D.CANTAB., F.R.O.P.,

PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL; CONSULTING PHYSICIAN TO THE METROPOLITAN HOSPITAL; EXAMINER IN PHARMACOLOGY AND THERAPEUTICS, UNIVERSITY OF CAMBRIDGE.

It is clear that in the time at my disposal nothing more than a very general review of this large subject can be attempted. The liver and pancreas are both developed as outgrowths of the alimentary tract, and their ducts are innervated in the same general way as the canal from which they develop. Their close co-operation is further shown in the way they pour their secretions into the alimentary tract at the same point, in their complementary rôles in the utilization of fat and in carbohydrate metabolism, as well as by the circulatory conditions which ensure that any internal secretion from the pancreas shall pass straight to the liver. Situated on the path by which all the blood from the digestive organs enters the systemic circulation, it is not surprising to find that the liver helps to prepare all three foodstuffs for utilization by the tissues. The bile it forms is at once an excretion and a secretion. But further, the liver is an important agent in detoxication and in maintaining the constant composition of the blood.

The earlier and simpler attempts to estimate the functional efficiency of the liver failed because its great reserve capacity was not realized. For, like the heart, lungs, and the kidneys, the liver does not normally exert its full activity, and so does not reveal its failure of function to ordinary tests until this has fallen to so low a limit that grave hepatic damage is no longer in doubt, and the time for successful treatment is past. Moreover, not only must the power of the liver to undergo compensatory hyperplasia be remembered, but, its various functions not being equally inhibited by disease, it is necessary to apply tests covering different fields of hepatic activity.

In the first place I shall consider tests related to the action of the liver in preparing the three foodstuffs for the tissues.

### I. TESTS FOR HEPATIC METABOLISM.

#### (1) Protein.

It has been clearly recognized for some years that the protein molecule is broken down into its ultimate amino-acids before absorption, and that these end-products are less toxic than the intermediate proteoses and polypeptides from which they arise. Further, as there is a chemical specificity of tissues, by no means all of such end-products are capable of being utilized for tissue repair at the time of their entering the blood stream. Those which cannot be used at once by the tissues are turned into urea and other excretory products. Indeed, the method of maintaining the nutrition of the body is as far as possible the same on an ample protein diet as in starvation. In both, amino-acids are used to make deficiencies good, though in starvation they are obtained by pooling the autolytic products obtained, as it were, by levying a tax on all the cells of the body. From this pool individual organs are allowed to draw, according to their functional importance to the body. But even in the well fed body the excess of protein food above what is required for tissue repair is not stored but excreted. Naturally, therefore, much more nitrogen is excreted by the well fed than by the starving body, any storage being provided from non-nitrogenous sources.

It would appear that each amino-acid has its own method of breakdown, and very probably its own ferment for achieving that purpose. This has been brought out clearly by Garrod in his study of the inborn errors of metabolism. He says:

"If any one step in the process fail, the intermediate product in being at the point of arrest will escape further change, just as when the film of the biograph is brought to a standstill the moving figures are left, foot in air."

Now it happens that most of such inborn errors as alkaptonuria, pentosuria, and cystinuria are inconvenient rather than serious. They are also rare, and although their study has established points of great theoretical importance as to protein

breakdown, they do not throw light on the estimation of hepatic efficiency. The ferments involved are evidently very resistant normally, since these substances do not appear in extensive degenerations of the liver, although porphyrinuria, which is sometimes an inborn error, may also occur in hepatic disease. The detection of leucin and tyrosin in the urine was thought at one time to be evidence of failure of the liver to turn them into urea, but they are now regarded merely as signs of hepatic disintegration. Though most prominent in acute yellow atrophy, they may be found in other diseases. Thus I saw them in a case of cirrhosis, where a severe hæmatemesis had been followed by coma for forty-eight hours, yet ultimately recovery took place. But it must be admitted that nothing has been found clinically to correspond to the experimental results obtained by Eck's fistula, even, for instance, after the Talma-Morrison operation, and certainly nothing that would form the basis for a test of hepatic inefficiency in respect of protein metabolism.

The nitrogen partition test aims at doing this by determining any loss of the dis-aminating and urea-forming functions of the liver. *A priori* one would expect to find that in failure of hepatic efficiency the urea excretion would fall, while the excretion of the precursors of urea such as ammonia and amino-acids would rise. But in practice we are met with the following difficulties: (1) Quite a small proportion of the total liver substance is adequate to make the normal amount of urea. (2) As so much of the urea comes direct from the food, the total amount excreted varies with the diet. On a liberal protein diet the urea forms about 85 per cent. of the total nitrogen, while in the healthy fasting individual it forms a much smaller proportion. This variation seriously affects nitrogen partition, without implying any disease. (3) An absolute increase in ammonia formation may be, and usually is, simply a protective step against acidosis, and is not evidence of a failure of urea formation. (4) Variations in the kidney threshold may materially affect nitrogenous excretion. This last difficulty can be surmounted by examination of the blood rather than of the urine, but the other three seem to me largely to vitiate the nitrogen partition test.

Again, in normal pregnancy de Wesselow and Wyatt have shown that a low urea excretion is the rule, because nitrogen is being diverted to the use of the foetus, so much so that a rise of blood urea above 40 mg. per cent., which would be within normal limits otherwise, implies a failure of renal function in pregnancy. This adds to the difficulty in applying nitrogen partition tests to the hepatic toxæmias of this condition.

#### (2) Carbohydrates.

All sugars are absorbed as monosaccharides. Although they can be rapidly stored in the liver and muscles, the absorption from the alimentary tract of any such sugar, with the important exception of levulose, leads to a rise of blood sugar from the fasting level of 0.1 per cent. to something like 0.16 per cent., falling again in about one and a half hours. This would imply that levulose, although its limit of tolerance tends to be rather lower than that of dextrose, can within that limit be stored as rapidly as it can enter the blood stream. Years ago H. Strauss regarded a diminished tolerance for levulose as evidence of impaired hepatic function, but this did not afford a satisfactory basis for a test. It is not sensitive enough, and the kidney threshold for the excretion of sugars is not a constant. Maclean and de Wesselow, having determined that levulose when given by the mouth in doses of from 30 to 50 grams does not raise the blood sugar in healthy subjects with an intact liver, went on to show that when the liver is defective it is not able to store levulose fast enough to prevent it from entering the blood stream, and thus increasing the blood sugar proportionately to the hepatic defect. This is the basis of the modern levulose test, which seems to me one of the best we have for hepatic efficiency. According to Spence, it shows that so-called catarrhal jaundice cannot be due to mere ascending catarrh of the main bile ducts, but must involve some hepatitis, since administration of levulose raises blood sugar in this disease even before the onset of jaundice. It has enabled several observers to show a similar change in safranine poisoning, while Mackenzie Wallis has found that in every case where a course of such an arsenical preparation has been given, some degree of hepatic inefficiency exists for at least three months. Clearly a second course should not be given within this interval; while, if levulose cause a rise of blood sugar of 0.05 per cent. above the fasting level, careful treatment is required, however slight the other clinical manifestations may be. In pure obstructive jaundice this rise of blood

\* A paper read to open a discussion at the Medical Society of London, March 12th, 1923.

sugar does not occur, or is very slight. As further evidence that catarrhal jaundice may involve a toxic hepatitis I should like to refer to a group of cases I saw last year where, in addition to a large and tender liver, with jaundice, there was cyanosis, air hunger, and almost complete suppression of urine, followed by intense albuminuria, sometimes with haematuria and casts. Yet the patients made a good recovery and soon became free from albumin. Sometimes they showed an increased diastase output, which might be held to prove pancreatic involvement as well.

It is perhaps convenient to discuss the diastase test here, even though this anticipates the subject of pancreatic tests. It was originally designed by Wohlgemuth as a test for renal efficiency. He took the amount of urine which could digest 2 c.c.m. of a 0.1 per cent. solution of starch paste in half an hour as the measure of its diastatic activity, which normally may range between 10 and 33.3 units. He claimed that if renal efficiency were impaired the output of diastase would fall. Working with Mackenzie Wallis in cases of war nephritis I was of opinion that this method of using the test was a guide to the amount of renal damage, for cases showing 5 units or less proved more obstinate than those with a more normal output. But subsequent work has shown that the diastase in the urine does not necessarily run parallel with the diastase in the blood, which is perhaps what we might expect from what we know of the behaviour of the kidney threshold towards substances useful to the body. The test has proved of more value in the recognition of pancreatic disease because here the alteration of the amount in the blood is so gross that the renal threshold is, as it were, flooded. In acute pancreatitis one might find 300 to 500 units—in one case of mine 1,000 were present—while in less acute cases 50 to 100 units may be found. In very chronic conditions there may be no excess, but even a deficiency. In ordinary clinical diabetes a low value is the rule. It was at first assumed that this diastase was merely pancreatic amylase reabsorbed into the blood stream, and was evidence of some obstruction to the pancreatic ducts, though in that case it would not be easy to explain its presence in normal urine. But Cammidge,<sup>2</sup> with Forsyth and Howard, has adduced cogent reasons for believing this diastase is hepatic in origin. The diastase value rises as more and more of an animal's pancreas is excised, right up to total extirpation. As it is clearly impossible for a non-existent gland to produce an enzyme, diastase cannot come from the pancreas. On the other hand, hydrazine phosphate, which has a toxic effect on the liver but not on the pancreas, reduces and may completely abolish the diastase output. These authors conclude that diastase is the agent which converts glycogen into sugar, and that its action is controlled by the internal secretion of the pancreas. If such control fails there is for a time a greatly increased production of diastase by the liver, though this may not by itself produce glycosuria. So far, however, though gross increase in diastase output certainly suggests pancreatic insufficiency, a defect of diastase in the blood has not helped much as evidence of hepatic insufficiency. Harrison and Lawrence<sup>3</sup> found in twenty cases of hepatic disease that the blood diastase was low in three severe cases. In two this rose again as the clinical condition improved. Certainly defective output in the urine could not provide such evidence because of the behaviour of the threshold of the kidney.

One thing appears clear about the glycogenic function of the liver: in the presence of an ample supply of glycogen the metabolism of the liver proceeds more smoothly. It was first stated that it was the antitoxic power of the liver which chiefly was affected by the glycogen store. But it seems more far-reaching than this, though it is certainly true that a liver is less liable to post-anaesthetic poisoning if it is well supplied with carbohydrate, while starvation, which would deplete the glycogen store, increases the liability to this catastrophe. And Colonel Harrison, at Maclean's suggestion, has found giving sugar, usually dextrose, of material benefit in preventing toxic jaundice after salvarsan. In a group of patients receiving sugar before injection there were only two or three cases, while in another group not receiving sugar there were nearly fifty cases of toxic jaundice.

### (3) Fats.

Leathes has shown that the fat normally present in the liver is in the more active unsaturated form, but that the fatty deposit which occurs there in poisoning by phosphorus or tetrachlorethane or after anaesthetics is in the more inert, saturated form. He makes out a good case for regarding as

a function of the liver the conversion of saturated fat into the more active unsaturated form for utilization by the tissues. When the liver is thrown out of gear by various toxins the tissues, starving for prepared fats, send unprepared fats to the liver, but in vain, for it is unable to deal with them. The liver may be compared to a miller—the saturated fats are the wheat he grinds and the unsaturated fats are the flour that results.

Foulerton pointed out that chloroform, ether, and tetrachlorethane are solvents of fat, while phosphorus, dinitrobenzol, and trinitrotoluene are readily soluble in fats, so that the destructive effects of these poisons on the liver may be due to their being conveyed with the fats to the liver in the attempt to carry out this process. In some cases, such as phosphorus or post-anaesthetic poisoning, this carriage of fats may lead to a gross increase in the size of the liver, but we require a much more sensitive test than this. Whipple devised the lipase test to this end. Normally blood contains a very constant amount of fat-splitting ferment, but in diseases of the liver this lipase is increased, as measured by the power of the blood to split ethyl butyrate. It has been supposed, therefore, that normally the liver inhibits the formation of lipase, so that its increase in the blood is a measure of hepatic damage. Whipple has applied this to chloroform poisoning, and Mackenzie Wallis<sup>4</sup> to salvarsan poisoning. The damage has, however, to be rather gross before the lipase increase is enough to be relied upon.

The latter observer has further reported that in toxic jaundice due to salvarsan poisoning the cholesterol in the blood is diminished, while in this condition and in phosphorus poisoning the liver is found loaded with cholesterol esters post mortem. This suggests that the liver normally plays the same part both in cholesterol and fat metabolism. It may be, however, that the cholesterol is merely on its way to be excreted in the bile, but the diseased liver cannot accomplish this. Its presence in the kidney under similar conditions may be an attempt at an alternative channel of excretion. In the toxæmia of pregnancy, including a case of icterus gravis, this cholesterol disturbance was not found.

## II. TESTS OF ANTITOXIC FUNCTION.

Apart from the reactions against bacterial poisons the antitoxic processes of the body are few and simple—such as toxic oxidation, reduction, hydration, dehydration, and methylation. The protective substances are few, and the process of rendering a poison harmless by conjugating it with a protective substance is most often carried out by the liver. Thus the toxic indol is conjugated with sulphuric acid into a harmless ethereal sulphate, indican. Although we regard marked indicanuria as evidence of intestinal toxæmia, we must remember that we are testing for that part of the indol which has been rendered innocuous. A more accurate method is to estimate the ratio between ethereal and total sulphates; the larger fraction the former constitutes of the latter the nearer are we to the limit of the antitoxic power of the liver. But if the liver cells are diseased such conjugation cannot occur, so that toxic substances like indol, skatol, and phenol can pass direct into the blood, even though the urinary output of ethereal sulphate is low. There does not appear to be any simple test for recognizing this.

Glycuronic acid is another important protective substance, and the formation of harmless glycuronates after administration of camphor, morphine, and the like is a function of the liver. It is claimed that 7½ grains of camphor given by the mouth should be completely conjugated with glycuronic acid and recognized by its reducing action in the urine, but if the liver is diseased no such glycuronic acid is formed. A simpler test is that introduced by Roch.<sup>5</sup> He gives half a grain of sodium salicylate an hour before food. This should be turned into a glycuronate which would not yield a purple colour with 1 per cent. ferric chloride solution. If the urine excreted for the four hours after a meal does give this colour hepatic insufficiency is present.

The hæmolytic crisis may also be regarded as due to a failure of the antitoxic power of the liver. As C. M. Wilson expresses it, under this rather forbidding name is concealed a test disarming in its simplicity. Widal<sup>6</sup> maintained that when the liver was diseased the normal post-prandial leucocytosis was replaced by a leucopenia, which was accompanied by a fall of blood pressure. This was believed to be due to the hepatic failure permitting the entrance of incompletely digested proteins into the systemic circulation. It recalls the anaphylactic reaction to material unsuitable for assimilation. Before breakfast a white count is taken, then 7 oz. of

milk are drunk, and another count taken twenty minutes later. Wilson concludes that, with the possible exception of the levulose tolerance test, this is the only test which gives an early warning of hepatic insufficiency.

### III. TESTS OF BILIARY FUNCTION.

Turning to the external secretion of the liver, the bile, we may first consider tests for alterations in its discharge into the bowel. The gall bladder not only regulates the occurrence of this discharge at the time it is required, but by adding cholesterol and mucin to the bile while absorbing water alters its composition, making it more concentrated and viscid. Therefore with complete obstruction to the cystic duct, the bile entering the intestine is unusually dilute. H. E. Griffiths<sup>7</sup> confirmed the general clinical impression that gall stones produce reflex hyperchlorhydria by finding this in 90 per cent. of the test meals on his cases. If this was not accompanied by regurgitation into the stomach there was usually x-ray evidence of marked pylorospasm. He attributes this regurgitation to the unregulated flow of bile into the duodenum which follows such diseases of the gall bladder as render it incapable of acting as a reservoir. A rise in the alkalinity of the duodenum at inappropriate times would relax the pyloric sphincter. This would occur when the cystic duct is occluded, or where the muscle of the gall bladder has been replaced by fibrous tissue as the result of prolonged disease, but would not follow complete obstruction of the bile duct, which would diminish the alkalinity of the duodenal contents. If it agrees with the other findings we may consider hyperchlorhydria to be the rule with disease of the gall bladder and bile ducts, while if there is regurgitation as well there is probably chronic disease of the gall bladder itself. Additional interest has been aroused in this part of the subject by the claim that if 1 to 4 drachms of magnesium sulphate in concentrated solution be introduced into the stomach a sharp flow of bile into the duodenum is excreted by reflex contraction of the gall bladder. By the use of an Einhorn tube this can be removed from the duodenum for examination. This claim has been disputed, and it is clear that if there is complete obstruction of the bile ducts the method is not applicable. But that it is occasionally of service is shown by a case in which I diagnosed inflammation of the gall bladder as the cause of dyspepsia. By this method purulent fluid was obtained, and at operation empyema of the gall bladder was found. Lyon<sup>8</sup> has extended this method by collecting three samples of bile by the duodenal tube. The first sample should be of transparent, yellow-golden colour from the common duct, the second darker and more viscid from the gall bladder, and the third much thinner and lighter in colour from the hepatic and intrahepatic ducts. By examination of these he claims that infection and inflammation of the various parts of the biliary system may be located.

If bile fails to enter the bowel the ill effects are principally due to the absence of bile salts, which may be regarded as the main secretion, the other ingredients being largely excretory. As they help in the emulsification and absorption of fats which have been previously split into fatty acid and glycerin by the pancreatic juice, the steatorrhoea which follows biliary obstruction is due to the increase of soaps and fatty acids in the stools, while in failure of the pancreatic secretion it will be the unsplit or neutral fat that will be in excess. Interference with absorption of proteins will lead to increased intestinal putrefaction with a consequent increase in the indican of the urine. The absence of bile pigment from the stools causes the familiar clay colour, but as the excess of fat may mask the presence of a small amount of bile we must not conclude from this colour alone that no bile is entering the intestine. Extraction of such faeces with acid alcohol or amyl alcohol may still show the presence of urobilin by the band in the blue of the spectrum or by green fluorescence on the addition of zinc chloride and ammonia. This would indicate incomplete obstruction, such as is usual with gall stones, while the entire absence of urobilin is suggestive of the more complete obstruction produced by new growth of the head of the pancreas. The presence of obvious bile pigment in the stools in a case of jaundice is, of course, against its being of obstructive origin.

I am obliged to Sir Humphry Rolleston for calling my attention to the phenol-tetrachlor-phthalein test. When phenolphthalein is given subcutaneously it is only excreted by the liver, but when this organ is damaged by phosphorus or chloroform, or when cholangitis is present, the output of the dye into the bile is diminished, as determined by faecal

analysis or by Einhorn's tube, and it appears in the urine. This test is naturally inapplicable when the common duct is completely obstructed.

*Van den Bergh's Test.*—Of late, however, interest has chiefly centred round the distinction between obstructive and toxic jaundice, based on van den Bergh's test. It has long been recognized that bile pigments originate from haemoglobin, but recently it has been urged by Brule<sup>9</sup> that the liver merely separates bilirubin from the blood as the kidneys do urea, and Whipple regards the star-shaped Kupffer cells of endothelial origin along the capillary walls as responsible for this work. Van den Bergh<sup>10</sup> has described two varieties of bilirubin, which can be distinguished in the serum by Ehrlich's diazo-reaction. In obstructive jaundice the test comes off directly, while in haemolytic jaundice the bilirubin, being linked with some constituent of the serum, does not give the reaction until the combination is broken up—for example, by alcohol. McNee has suggested that it is normally the work of the Kupffer cells to do this, and that when they are damaged the bilirubin escapes this modification and gives the indirect reaction only. Dr. Christopher Andrewes has been trying this test at St. Bartholomew's Hospital, and I am much indebted to him for placing his as yet unpublished results, based on 108 cases, at my disposal. He says:

"Practically all the cases are compatible with the theory that the direct reaction is due to obstruction (either of larger or finer ducts) and that the indirect reaction is due either to disordered function of liver cells or to increased haemolysis. So that the cases might be classified into (1) gross obstruction, including cholelithiasis, new growths, etc.; (2) haemolytic jaundice, such as in the factors of liver necrosis; (3) conditions such as in which the factors of liver necrosis can probably occur together or separately. Other observers have found that cases of this third group may give an indirect reaction at first, and go through a biphasic to a direct reaction. It is this mixture in many diseases which seems to me to limit seriously the clinical value of this test. My cases of catarrhal jaundice show 8 direct reactions. Others have found more numerous cases giving indirect reactions. Schiff and Eliasberg<sup>11</sup> in an 'epidemic' in children found all indirect reactions at one stage and all direct reactions at another."

The general conclusions to which Dr. Andrewes comes are these:

1. As a test of liver function it is very gross, being, however, a little more sensitive than clinical evidence of jaundice. Thus several cases of cirrhosis gave normal results.
2. As an aid to diagnosis of the cause of jaundice, it is of very little value. A well marked indirect reaction indicates catarrhal jaundice rather than stone. A direct reaction may mean either.
3. In anaemia an indirect reaction above normal indicates a haemolytic cause, probably pernicious rather than secondary. The test is probably rather more reliable than examination for urobilinuria.
4. The estimation of bilirubin in blood-stained fluids (pleural, peritoneal, cerebro-spinal) can decide whether the bleeding is old or produced at the time of puncture.
5. With direct reactions above 3.5 units, bile will be present in the urine; with direct reactions below this figure, and with indirect reactions, bile will be absent there.

One must conclude, I fear, from this careful study, that in its present form the test is of very limited value. It will be noted that the levulose test has given more positive evidence than van den Bergh's that catarrhal jaundice is often a hepatitis.

*The Fate of the Bile Pigment.*—It will be gathered from what I have already said that I lean to the view that urobilin or its chromogen is formed in the intestine by reduction of bile pigment through bacterial agency. The evidence in favour of this seems very strong, for when all bile escapes through a biliary fistula, or when complete obstruction prevents bile from entering the intestine, no urobilin is found. Again, it is absent from the faeces at birth, not appearing till bacteria have had time to establish themselves in the bowel, while if bilirubin is inoculated with intestinal bacteria urobilin is formed. Normally this urobilin colours the faeces, where it is often called "stercobilin," while a small amount is reabsorbed and appears in the urine. If there is polychromia from increased haemolysis there will be increased formation of urobilin, while if there is partial or complete obstruction to the bowel there will be increased reabsorption of urobilin. In either case urobilinuria will occur, but it has most significance as evidence of haemolysis. Against this view has been urged the presence of urobilin in the duodenal contents—that is, above the point at which bacterial activity begins. But I do not think this is sufficient to counter-

balance the mass of evidence in favour of the intestinal origin of urobilin. I am aware that urobilinuria is often regarded as evidence of "floating gall stones" or of cholangitis. I can only say I have far more often seen this diagnosis made than confirmed, when based on this test.

Bile salts in jaundice are by no means always to be found. Matthew Hay's test with flowers of sulphur is the simplest way of detecting them. I have found them present at the beginning of obstructive jaundice, and in one case even before bile pigment appeared in the urine. But later on they are generally absent, probably in part because the biliary cycle is interfered with. When bile is drained through a fistula the amount of bile salts in it soon sinks to one-tenth of the normal (Copeman). This suggests that the reabsorbed bile salts are used over again ten times. Naturally, then, in obstructive jaundice such bile salts as escape into the urine at the beginning are permanently lost, and the amount available sinks below the kidney threshold. In toxic jaundice bile salts are not likely to appear in the urine at any stage, both because they can get into the bowel and because their formation throws greater labour on a diseased liver than the excretion of bile pigment. The presence of bile salts, therefore, in the early stages of jaundice suggests an obstructive rather than a toxic cause.

#### IV. TESTS FOR PANCREATIC INADEQUACY.

I can deal quite briefly with this part of my subject, because our views have now crystallized into something like definite form.

##### (1) Signs of Defective External Secretion.

(a) *Failure of Tryptic Digestion.*—Unaltered muscle nuclei may be found in the faeces after a meat meal, but this is not always easy to do, nor does it help much to stain the muscle fibres and give them with lycopodium grains as a guide. Sahli's method of administering iodine in gelatin capsules hardened by formalin, and testing for iodine in the urine and saliva, cannot be recommended. It is also claimed that trypsin can be demonstrated in normal stools by placing a small quantity of faeces on a gelatin plate, when a small area of digestion will result. Apart from detection of muscle nuclei I have not found these methods much help. A negative result is of no value.

(b) *Failure of Starch Digestion.*—Starch granules may be detected in the stools after unboiled starch has been given. Boiled starch can be digested by saliva. Chronic pancreatitis may cause oxaluria from intestinal fermentation of carbohydrates (Cambridge and Mayo-Robson).

(c) *Failure of Fat Digestion.*—As already explained, the steatorrhoea of pancreatic defect takes the form of an excess of neutral, unsplit fat. This is the most valuable of the tests for deficient external secretion.

##### (2) Signs of Defective Internal Secretion.

(a) *Diminished Sugar Tolerance.*—This may be expressed in glycosuria, and almost certainly in hyperglycaemia, two hours after a dose of 50 to 100 grams of dextrose. The normal tolerance for dextrose is 150 to 200 grams. It must be remembered, however, that this may be a comparatively late symptom, and that it can be also produced by chronic alcoholism, hyperthyroidism, hyperpituitarism, and probably by hyperadrenalism.

(b) *Diastase Test.*—This has already been discussed. In my opinion it is one of the best tests for recent pancreatic damage.

(c) *Adrenaline Eye Test.*—Loewi showed that if adrenaline is instilled into the eye the pupil does not normally dilate. But if the pancreas is inadequate the pupil dilates in twenty to sixty minutes after one drop of the 1 in 1,000 solution is instilled, and another drop five minutes later. This is based on the antagonism between the adrenals and pancreas, of which there is other evidence. But if there is hyperthyroidism the test may also be positive, as this upsets the balance by reinforcing the adrenals. The dilatation is often an eccentric one. The test may fail if repeated within a week. Taken in conjunction with other signs, it is a simple test of some value and is easily applied. Recently, however, I saw a positive reaction in a case of acute appendicitis.

##### (3) Signs of Pancreatic Disintegration.

(a) If pancreatic lipase escapes into the circulation it can be found in the urine by the ethyl butyrate method (Opie).

(b) A pentose may sometimes be found in the urine from the breakdown of pancreatic nucleo-proteins. This is also the

basis of Cambridge's test, which, however, does not seem to be very much relied upon at the present time.

To sum these tests up: If the adrenaline eye test and the diastase test are negative it is seldom worth while to undertake more elaborate investigations. If they are positive, and there is excess of unsaponified fat in the stools, it is very suggestive of pancreatic disease. If there are also muscle nuclei in the stools, it greatly strengthens the diagnosis. If all these signs are present in addition to glycosuria, the diagnosis is almost certain.

But here, and still more with the liver tests, clinical evidence must not be neglected. When Falstaff asked his page, "Sirrah, you giant, what says the doctor to my water?" the boy replied, "He said, Sir, the water itself was a good healthy water; but for the party who owned it, he might have more diseases than he knew for." I think I know that doctor; entrenched in the laboratory, he is quite prepared, without seeing the patient, to diagnose the existence of many more diseases than the medical attendant ever "knew for" or even suspected. The reaction against this was shown in a recent discussion on renal tests, when several surgeons expressed their willingness to abide by clinical signs alone. I am neither so bold nor so sceptical, but I would urge that these laboratory tests are still themselves on trial; and that the ultimate diagnosis must rest on the clinical as well as the biochemical findings.

## THE USE OF RADIUM IN THE TREATMENT OF DISEASE.

BY

DAWSON TURNER, M.D.,

IN CHARGE OF RADIUM TREATMENT AT THE EDINBURGH ROYAL INFIRMARY.

IN a previous paper published in this JOURNAL (January 20th, p. 100) I discussed the dosage of radium; I now desire to deal briefly with the principal conditions in which radium has been found useful in the Edinburgh Royal Infirmary. They include malignant disease, exophthalmic goitre, spleno-medullary leukaemia, Hodgkin's disease, keloids, and naevi.

The records show that radium has been chiefly used for malignant disease, and on the whole with encouraging, and in some cases with excellent, results. As cases of undoubted malignant disease, confirmed by operation and pathological examination, which remain perfectly well for more than seven years after the primary treatment are relatively rare, I quote the following case of recurrent sarcoma:

A woman, aged 49, recommended by Dr. MacLagan of Ayrton, had developed sarcoma four years before. Several operations for the removal of the growth were unsuccessful. She was admitted to the Royal Infirmary by Mr. Miles on July 15th, 1915. A large nodular mass projected in the left suborbital region; it interfered with vision and was adherent to the maxilla. Pathological examination showed that it was a large spindle-celled sarcoma. As Mr. Miles considered the tumour inoperable, radium treatment was recommended. By internal and external applications a dose of 5,180 milligram hours was given. In November, 1915, a further external dose of 5,180 milligram hours was given. During the applications the growth diminished markedly. In February, 1916, the tumour had greatly shrunk and was movable; it had been fixed before. The patient was better, stronger, and could see normally. The condition had so much improved that Mr. Miles removed what was left of the growth; this was followed by a prophylactic dose of 4,120 milligram hours. In November, 1916, the growth had disappeared and Mr. Miles could detect no sign of recurrence. Seven years have now elapsed since the radium treatment was begun, and Dr. MacLagan writes on January 19th, 1923: "The patient keeps well without any trace of recurrence."

Of malignant affections, rodent ulcers, epitheliomata, lympho-sarcomata, spindle-celled sarcomata, malignant disease of the cervix, sarcomata of the nasal passages, and of the non-malignant affections, exophthalmic goitre, early keloids, and certain naevi are, in my experience, very amenable to radium treatment. They might be termed first-class subjects, because they admit under favourable conditions of actual cure. Under second-class subjects—meaning thereby conditions which may be ameliorated but in which a cure can rarely be expected—might be placed carcinomata, lymphadenomata, and spleno-medullary leukaemia.

Small rodent ulcers not affecting the mucous membrane or bone are easily cured by a dose of from 500 to 800 milligram hours through a filter of silver,  $1\frac{1}{2}$  mm. thick. A much smaller dose would suffice to cause the ulcer to heal over, but it would probably recur. Rodent ulcers at the side of the nose where the alae nasi join the cheek are more refractory; so too are those affecting the ear and just below it. Unless completely cured by the first applications they tend to become radio-resistant and further exposures may do harm.

Small epitheliomas of the lip are quite amenable to surface applications. I have had tubes prepared with an eyehole at each end so that they can be sutured by both ends to the lip and maintained in close apposition to the growth for the necessary time. When the floor of the mouth, tongue, or fauces are attacked the condition is difficult to benefit materially by radium.

Of all new growths the most susceptible to radiations are the lympho-sarcomata. They melt away in a surprising manner but tend to recur or form metastases. Sarcomas affecting the nasal passages are favourably influenced by radium. The writer has had cases which have remained free from the disease for many years and still are free.

Much experience has been gained in recent years regarding the use of radium in gynaecology, but I must limit myself in this article to a few general remarks. In malignant disease of the external genitals treated by radium the prognosis as a rule is bad; in early and limited disease of the vaginal wall the prognosis seems better, and I have seen one complete cure. It is in early malignant disease of the cervix that the best results are obtained; all observers are agreed upon this. Big doses of 6,000 to 10,000 milligram hours should be given, and at the first treatment. Smaller doses repeated are a mistake. Recurrence, after a longer or shorter interval, is, however, the rule, because of the difficulty of efficiently raying the more distant portions of the disease. Few cases are sent for radium treatment which are not in an advanced condition; even in these cases, however, some improvement is always observed both locally and generally. Pain is relieved, discharges cease, ulceration heals, and the patient gains in general health, strength, and weight. An important question is, How far does the beneficent activity of radium extend? Professor Bumm found in post-mortem examinations of the radiated cervix that cancer cells were only destroyed to a distance of three centimetres from the radiating source. It must, however, be remembered that the sphere of beneficent activity would depend upon the length of the exposure as well as upon the quantity of radium—the longer the exposure the greater the cumulative effect upon outlying cells; moreover, those cancer cells, which appeared to Professor Bumm to be normal, may yet have been rendered incapable of proliferation. Wassermann radiated small bits of mouse cancer *in vitro*. In certain experiments the tumour retained its vitality when inoculated, but did not grow. He concluded that the rays did not kill the cancer cells, but stopped their power of proliferating.<sup>1</sup>

Exophthalmic goitre is a condition for which in recent years radiation has been found consistently useful. The writer has now treated with radium upwards of 200 cases, and with two exceptions all derived more or less benefit both in their general condition and special symptoms. Thus the patients regain strength, put on weight, and lose the tired feeling, and at the same time the tachycardia, tremor, and breathlessness are diminished and may disappear altogether. Not much change need be expected in the size of the thyroid or in the exophthalmos, except in early cases. It is well to warn patients of this lest they suffer disappointment; but operative measures might now be considered, to reduce the size of the gland, both because its vascularity is diminished and because the patient is better able to stand an operation. A dose of 300 to 500 milligram hours, properly screened so as to avoid injury to the skin, may be given to each lobe, to the isthmus, and over the thymus. The latter organ should not be neglected. I have had cases which were somewhat refractory so long as the applications were confined to the thyroid but which yielded rapidly when the thymus was exposed.

Under second-class subjects recurrent scirrhus nodules, even when attached to or growing from the bone, will disappear; but they recur. Carcinoma of the rectum is refractory except in limited annular strictures, where, by placing tubes inside the stricture considerable benefit may follow. In Hodgkin's disease amelioration may be expected by applications over the glands or by burying tubes inside them. In

spleno-medullary leukaemia, by exposures over the spleen it will be reduced in size, the white blood corpuscles diminished, and the general health improved; but in a few months the patient will return with a recurrence; this will again yield to treatment, but will be followed by another recurrence, and each recurrence requires larger doses, and in time the patient succumbs. The following case with graph illustrates the fall in white blood corpuscles following the application of radium.

A man, aged 32, suffering for the last nine months from spleno-medullary leukaemia, was recommended by Professor Gulland for radium treatment in April, 1921. The spleen was considerably enlarged but did not cross the middle line. The white blood corpuscles numbered 310,000. He was given a dose of 3,000 milligram hours, screened by  $1\frac{1}{2}$  mm. of silver over the spleen. This produced a good effect, the spleen decreased, and in two months, when he was discharged, the white blood corpuscles numbered 9,600.

For four months he remained fairly well, but was then readmitted; the spleen had crossed the middle line and was also lower down. The white blood corpuscles had increased to 316,000. A dose of 5,120 milligram hours was now given under the same conditions as the previous one. In a fortnight the white blood corpuscles numbered 136,000 and he was discharged.

He had no further treatment until June, 1922, when the spleen was found to be just over the middle line and the white blood corpuscles numbered 250,000. A dose of 4,800 milligram hours was given. In a week's time he felt much better, the white blood corpuscles had fallen to 152,500, and he was discharged.

In three months (November, 1922) he was readmitted in a worse condition; the spleen was hard and reached to within one inch of the umbilicus, the liver was enlarged and painful, and the white blood corpuscles were up to 300,000. He was now given a larger dose, amounting to 9,000 milligram hours. In a week he felt better, and the white blood corpuscles had fallen to 80,000. He was able to return home, but a month later died suddenly.

In the treatment of exophthalmic goitre and of naevi in children by radiation, radium has the following advantages as compared with the x rays: (1) Absolutely constant emission of rays, and therefore exact dosage possible. (2) Greater penetration of its rays, so that the deeper parts are reached. (3) Saving of time, as the radiation is maintained night and day until the necessary dose has been administered. (4) No noisy, exciting apparatus, so that the treatment can be applied at the bedside without in any way alarming or disturbing the patient.

## SUDDEN DEATH FROM ANAPHYLACTIC SHOCK.

BY

LIEUT.-COLONEL F. W. SUMNER, M.D. CANTAB.,  
F.R.C.S. EDIN.,  
INDIAN MEDICAL SERVICE.

In my capacity of medical officer to a girls' school in Simla I was called, in October, 1922, to see a sick girl; the condition of the throat was suggestive of diphtheria, and a throat swab confirmed the suspicion. I advised the head mistress that all contacts be given a prophylactic hypodermic injection of diphtheria antitoxin and be segregated for fourteen days, and that the rest of the school be placed out of bounds. This was agreed to.

The syringe I used for inoculation was one of 10 c.cm. capacity; it was thus capable of holding the contents of several  $2\frac{1}{2}$  c.cm. bottles (each containing 2,000 units), and it

was possible to inject several girls out of one syringe-ful. The routine was as follows: A girl in room (1) would have her loin uncovered, would come into an adjoining room (2) and lie on a couch; here iodine would be applied; she would receive 1,000 units, and, holding an iodine swab to the needle-hole, would pass on to an adjoining room (3).

As I was injecting the fourth girl (the first and second girls being sisters), out of one and the same syringe-ful, a mistress hurriedly came to me from room (3), saying that a girl (the second of that syringe-ful) was not feeling well. I immediately went and found this girl (aged 8) lying on a bed; she was obviously *in extremis*, was foaming at the mouth, and breathing in a very shallow manner; her pulse was scarcely perceptible; she was almost comatose, making no sound, and incapable of speech. She was lying on her right side and was endeavouring to turn on to her face; there was some cyanosis of her face and congestion of her conjunctivae, with protrusion of her eyeballs; the region round her nose was pallid in comparison with the rest of her face; the lower part of her face had the appearance of being somewhat swollen, as also the tongue and mouth; there was no rigidity or spasm of muscles.

I immediately commenced artificial respiration, controlled the tongue by a ligature passed through its tip, periodically swabbed the mucus out of the fauces, got the head low down, had the trunk massaged, and gave a stimulant hypodermically; but there was no response or sign of life after the first minute or two. Nevertheless, the artificial respiration was kept up for half an hour.

The condition of the girl during the interval between her leaving room (2) and my seeking her in room (3)—about one to two minutes—I found, by questioning the mistress there present, to be as follows: "On entering room (3) she stood for a few seconds and laughed with the other girls; she then started whimpering, and said, 'My throat is paining me.' She began to cough, a kind of cough which a child gives who is forcing herself to cough and making herself sick; she did not stagger; her face went white round the nose and mouth (she was normally a pale child); a utensil was brought to her as it was thought she might be sick. She was then placed on the bed on her back; she foamed at the mouth, turned on her right side, had some slow movements of her left hand and arm; there was no twitching or other movements of muscles."

She had never had any previous injection of any sort.

No other of the ten cases injected had any anaphylactic symptoms, nor had the diphtheria child herself, who was given a large curative dose.

Deceased was, I understand from the school mistresses (never having myself seen her previous to this occasion), a girl of average size for her age, rather heavy in the face, and one who struck them as having enlarged tonsils and adenoids.

A careful investigation of her history brings out the following points:

1. She was always apparently a healthy child.
2. She had had only one illness, bronchopneumonia, in 1918.
3. She was subject to colds.
4. She slept with her mouth open.
5. A wheezing at her mouth could be clearly and frequently heard; a doctor said she had asthma.
6. In 1917 she was examined in St. George's Hospital, Lucknow, where the report is stated to have been: "It was necessary that the bone of her nose at the back should be scraped."
7. Her eyes would become inflamed and her nose would run whenever she took a drive behind horses, which was a frequent occurrence, but this would not happen after a motor drive; this lasted up to 1920, since when the symptoms did not occur although she had a drive behind horses every evening for months.
8. She never allowed the top button of her dress to be fastened; she gave no reason for this. (Enlarged thymus gland?)
9. She had had a fainting attack three weeks before after a heavy picnic lunch; she did not get out of breath easily; she, generally speaking, was pale and looked puffy under the eyes.
10. She had been at school for several months, and there had been no necessity to bring her to me for any treatment or examination.

#### Family History.

She had one sister and two brothers; the sister was at the same school, was quite healthy, had had no illnesses, and was given a prophylactic injection at the same time as her own fatal one. One brother died of heart disease after rheumatic fever; the other brother had congenital heart disease (a patent foramen ovale being diagnosed); his face was of a grey colour for six months, but this has passed off and the boy is apparently quite well.

Her father's brother, six years after a heat-stroke, died

suddenly within an hour; "a necropsy was done and a large blood clot found in the head."

There is no history of bleeders in the family, and no consanguinity of the parents.

#### Remarks.

In this case the striking features are:

1. The likelihood of a condition of "status lymphaticus" with probable enlargement of the tonsils, adenoids, and persistent thymus.
2. The intolerance to the vicinity of horses during life (conjunctival, nasal, and bronchial catarrh and spasm resulting).
3. The intolerance to the subcutaneous injection of horse serum, causing rapid death.
4. The individuality of the intolerance; deceased's sister was one of the girls injected from the same syringe-ful and suffered no ill effects.
5. The diagnostic cry, "My throat pains me."
6. The diagnostic frothy viscid mucus on the lips.
7. So rapid a fatal result occurring within five minutes after injection is unique in a human being, though such rapid effects were experimentally produced in dogs.
8. Severe anaphylaxis is a rare occurrence after a first injection of serum, anaphylactic shock being still rarer, and fatal anaphylactic shock practically unknown. A very rough estimate of the mortality from anaphylaxis among first injection cases at 1 per 1,000,000 and among subsequent injection cases at 1 per 10,000 would not be wide of the mark.
9. The sudden death was such an unexpected and overwhelming blow to the parents that an autopsy was out of the question.
10. A War Office pamphlet entitled *Memorandum on the Use of Curative Sera* says: "It may be remarked that sometimes anaphylactic shock occurs after a primary injection of horse serum such as is given in diphtheria, especially in persons suffering from Graves's disease, or subject to asthmatic attacks, or who are affected by emanations from horses. But this is so rare (1 in 50,000) that it may be ignored in practice."

The post-mortem changes as seen in Professor Dean's case<sup>1</sup> of a soldier dying of anaphylactic shock following antitetanic serum injections, Gurd, Fraser, and Roberts's similar case<sup>2</sup> and anaphylaxis studies in dogs<sup>3</sup> show, in brief, that, with a rapidly occurring death from anaphylactic shock, the primo lesion is in the liver, consisting of engorgement with leucocytes, and haemorrhage into its substance; there is pro- leucocytes, and haemorrhage into its substance. This found disturbance and death of the liver elements. This acute and fatal turmoil of the liver may be compared to that occurring in late chloroform poisoning and in the eclampsia of pregnancy. A similar engorgement of the lungs occurs, becoming more and more marked the longer the patient lives; death results from oedema of the lungs.

These deaths, appallingly sudden and unexpected and regrettable, merge, however, into insignificance when one reflects on the enormous saving of life by the use of various serum injections—for example, tetanus in the great war, and diphtheria in civil life; the risk to life is less than that of the most trivial surgical operation.

Doubtless in process of time the vehicle of the antibody content—the horse serum—will be modified in some way to prevent any chance of anaphylaxis occurring, whether by using some other less toxic animal serum or by adding some protective bodies to give it a colloidal character.

Till such a time a preliminary intravenous injection of 1/2 c.c.m. of the 10 per cent. diluted serum and, if no adverse symptoms arise in an hour, the subcutaneous injection of remainder of the dose should eliminate the possibility of anaphylactic disaster; a preliminary intravenous injection of sodium carbonate 5 grains, gum arabic 1 drachm, glucose 1 drachm, in normal saline solution up to 30 c.c.m., together with an intramuscular injection of a sterile solution of 1 grain of calcium chloride dissolved in 10 minims of normal saline solution an hour before the serum injection, should also do away with any chance of anaphylaxis.

## AMPUTATION AT THE SHOULDER.

BY

F. R. PARAKH, M.D., M.R.C.S.,

CONSULTING SURGEON TO THE SURAT GENERAL HOSPITAL, INDIA.

DURING the last eighteen months I have seen three cases of rapidly growing endosteal sarcomas of the upper end of the humerus, growing into the shoulder-joint, and with distinct enlargement of the axillary glands, which required immediate and complete amputation. In the first two cases I followed the old and recognized method of first dividing the clavicle for ligation of the main vessels and exposure of the cervical plexus, before proceeding with the interscapulo thoracic amputation. In the first case, which was one of a very thin and emaciated male, I had some difficulty in getting at the main vessels, although I had taken good care to remove as much of the clavicle as circumstances demanded. It took me nearly thirty-five minutes to do this part of the operation, and I was disappointed at the time lost in this preliminary step. The second patient was a well developed young man weighing 155 lb. The operation was commenced in the usual way, and many difficulties were encountered in satisfactorily exposing the vessels and plexus. It took me nearly two and a half hours to complete the operation, and, possibly owing to the length of time and the shock of the operation itself, the patient died four hours after the operation.

In July, 1922, the third case was admitted to hospital, and, as previous experience of the two former operations was anything but happy, I made up my mind not to divide the clavicle, but to try to ligate the vessels as the first step of the operation. As the growth was much more marked in the front than the back and invading the joint, I made a large flap, commencing from the clavicle near the sterno-mastoid attachment, carried it along the axillary border of the scapula down to its angle, divided the muscular attachments of the scapula, and, as the whole extremity fell forwards of its own weight, there was very little difficulty in getting at the deep vessels, with which I immediately dealt. The whole operation did not last more than fifty minutes and was done with comparative ease.

I must confess that I had never heard nor read of the above method of doing the operation until, soon after my third operation, I received the BRITISH MEDICAL JOURNAL of March 11th, 1922, and I was gratified to find on page 381 an article describing more or less exactly the above procedure by no less an authority than the late Mr. H. Littlewood. With me it was only a case of necessity being the mother of invention, without any previous experience of such dissection either on the cadaver or the living subject.

## DERMATITIS FROM DYED FUR.

A CURRENT epidemic of "fur dermatitis" among out-patients is worthy of notice.

Except for degree of reaction, the type of dermatitis has not varied, and the patients mostly entered the department with its etiology on their shoulders. The eruption was limited to the lateral aspects of the neck and to the chin, but in one case the mucous membrane of the lips was dry and cracked, and in another, after three months of facial involvement, the reaction had spread to the forearms. A greater or less degree of oedema of the eyelids was, or had been, present in all the cases. This is a common and well recognized symptom of dermatitis artefacta from the use of hair dyes.

The eruption consisted of a blotchy erythema, limited in the early cases to the lateral aspects of the neck and face, but spreading thence, in cases of over a month's duration, to the whole of these areas, and resulting in considerable oedema and disfigurement. The later cases showed pronounced infiltration, with a tendency to vesiculation and "weeping." Itching and burning were complained of in a degree transcending the clinical manifestations, and in one case had prevented sleep for several nights.

The diagnosis from seborrhoeic dermatitis—the only dermatosis at all resembling it—rested on the localization, the absence of scalp involvement, and the history. In every case the direct association by contact of the fur collar with the neck and chin could be demonstrated, and none of the

patients had ever suffered from "eczema" antecedent to their purchase of the coat. Further support to the diagnosis was obtained in two cases by applying a scrap of the fur under strapping plaster (and against a control) to the anterior aspect of the thigh. Erythema occurred in both subjects of the experiment where the fur was applied within twenty-four hours of the application.

The coats responsible all had fur collars of a dark flat variety, of very poor quality, and known to the trade as "dyed coney." It is probably rabbit fur dyed by one of the paraphenylenediamine group of textile dyes. A sample has been submitted to expert investigation, and an attempt to trace the place of manufacture will be made.

HENRY C. SEMON, M.D.

## TRAUMA AND APPENDICITIS.

WHILST visiting a patient I was requested to examine a boy belonging to the same household. I was informed that three days previously he was struck in the abdomen by a perambulator, and that since then he had complained of violent pain. The high temperature, rapid pulse, tenderness over McBurney's point, and rigidity of the right rectus muscle gave me the impression that the boy was suffering from appendicitis. I visited him early the following morning and found that the temperature was still high and the pulse very rapid, and in addition he was doubled up with pain. I advised removal to hospital, where he was operated upon that afternoon. Laparotomy revealed a gangrenous condition of the appendix. Recovery was retarded by an attack of bronchopneumonia; but eventually the boy left hospital fit and well.

## Reports of Societies.

## THE VALUE OF LABORATORY INVESTIGATION IN DISEASES OF LIVER AND PANCREAS.

A DISCUSSION on the value of laboratory investigation in diseases of the liver (including the biliary system) and of the pancreas took place at the meeting of the Medical Society of London on March 12th. Lord Dawson of Penn presided, and the discussion was opened by Dr. W. LANGDON BROWN with a paper which is printed in full at page 461.

Dr. F. LANGMEAD, after a reference to Dr. Langdon Brown's excellent and exhaustive treatment of the subject, said that he himself had approached this matter in the endeavour to apply laboratory tests to the elucidation of the cases which came forward in ordinary hospital practice, and to gauge to what extent these tests might form part of the practitioner's armamentarium. At the outset the number of the tests was a disadvantage; in medicine numbers were a weakness, not a strength. If by the "value" of this investigation the immediate practical usefulness of the laboratory test was intended, it must be confessed that, excluding the blood-sugar estimation in suspected or true diabetes, the tests had at the moment little usefulness from the point of view of ordinary diagnosis. With the exception just mentioned, he could not recall any instances within his own experience in which a laboratory test for the efficiency of the liver or the pancreas had provided him with a correct diagnosis which otherwise would have been missed. He did not mean that the test usually failed to correspond with the clinical findings, only that one was never first put upon the right track by means of the test. Discussing the tests individually, he said that the diastase content of the urine was a test which was losing rather than gaining adherents. The fat content of the stools was more helpful, but it could not be relied upon to decide, save in a case of obstructive jaundice, in what organ lay the disease. The levinose test was applicable mainly to acute destruction of the liver cells, and could not be depended on for chronic cases. He would be sorry to appear to speak disparagingly of tests so scientifically worked out, but there was a danger of the efficiency test being accepted as a kind of "ready reckoner," and he held strongly that the investigation was not sufficiently matured to permit of this.

Dr. J. W. McNEE was very much in agreement with Dr. Langmead. The subject was still only at its beginning, and the time was not ripe for a full-dress discussion. It was obvious that no one test could give information in more than one or two directions. The levinose test, for example, had

definite value only in acute conditions of the liver—in cases in which there was hepatitis or toxic damage of the liver cells; the usefulness of the lipase test also was confined to cases of acute damage, and in more chronic hepatic diseases had nothing like the same value. He was extremely doubtful as to tests which involved the use of Einhorn's tube for taking out the contents of the duodenum. With regard to tests which concerned the pigmentary metabolism of the liver, he had been doing a good deal of work on van den Bergh's test for distinguishing obstructive and toxic jaundice. The chief value of this test in hepatic diseases was that it had transferred the general idea with regard to bile pigments away from the urine and faeces back to the blood. This had opened up a view of latent jaundice which had definite value. With regard to its direct application in practice to clinical cases, all he could say was that when there was complete direct reaction he had never had any difficulty; cases in which there had been complete indirect reaction had been either cases of haemolytic jaundice or of catarrhal jaundice, but not all the latter gave this reaction. At first he thought that all cases of catarrhal jaundice would give the indirect reaction, but he had found that this was not so. His conclusion was that none of these tests alone provided much information of value, though some of them might be useful.

Dr. MACKENZIE WALLIS agreed that no one test would give any valuable information. Only by a combination of tests could information of value be obtained. The most positive results were obtained in acute injuries to liver and pancreas. The investigation of salvarsan jaundice furnished an opportunity of applying the various tests and working out their relative values. The results he had himself obtained in salvarsan injections led him to recognize that the levulose tolerance test had the advantage of being extraordinarily accurate and delicate; it gave evidence of liver injury which no other test could furnish. Its disadvantage was the time it occupied, but a simplified method had been worked out. Another test which yielded interesting results in salvarsan cases was the lipase content of the serum. This by itself was of little value because it was not so delicate as the levulose test, and when it was positive it signified that considerable damage to the kidney cells had taken place. Like other speakers, he was sceptical of the Einhorn tube method of investigating biliary function. With regard to tests for pancreatic inefficiency, he drew attention to an investigation which he and Mr. H. E. Griffiths had made on gall stones. A large number of cases, both obvious and obscure, were investigated, and as many tests as possible were applied. These were particularly favourable cases to investigate from the point of view both of liver function and of pancreatic function, because they mostly came to operation, and there was no possibility of further appeal, for either they had stones in the gall bladder or they had not, so that the diagnosis, whether based on clinical or laboratory findings, was either proved or disproved. In a large number of cases of gall stones he and his colleague found that there was hyperchlorhydria with regurgitation. The lipase content of the blood was raised in some and normal in others; diastase in the urine was considerably raised in several. In conclusion, he emphasized the importance of not placing reliance on one test alone. One test taken by itself would often give false results. If these tests had not been of value in diagnosis, at least they had been useful in the scientific investigation of problems connected with hepatic and pancreatic function.

Dr. E. C. DOBBS thought that the majority of workers were too apt to ignore the physiology of the liver when dealing with these problems. The recent researches of Mann had shown that four-fifths of the liver in animals might be removed without any symptoms beyond transitory shock. Apart from disturbances due to operative interference and interference with external secretions, there was little or no ill effect experienced from destruction of the liver until almost the whole had been removed. Unfortunately the majority of reactions for liver efficiency did not seem to give any idea with regard to the prognosis or the seriousness of the lesion. In his own experience one of the most valuable tests was that which depended upon the action of the liver in forming glycuronic acid with compounds such as camphor.

Dr. G. A. HARRISON said that in acute or subacute pancreatic disease the diastase test had been most useful, but generally it was of no assistance in chronic lesions. With regard to the tests of liver efficiency, most of the cases he had been asked to investigate had gross clinical signs, and from the clinician's point of view the test generally gave but little assistance. The point that had struck him most

was the frequency of coincident disease of liver and pancreas—so much so that he had made it a rule to test the efficiency of both organs. Unfortunately it was difficult to test one organ to the exclusion of the other. The new levulose test might be affected by deficiency of the internal secretion of the pancreas, and one could not be absolutely certain as to what it meant. Van den Bergh's test was a laboratory test of real value, but only when its results were taken in association with other findings. All the tests must be weighed carefully in conjunction with clinical evidence; they should be regarded as an extension of the clinical examination, not in any respect as a substitute for it.

Mr. H. E. GRIFFITHS regarded it as unlikely that one infallible test would be found for a disease of one organ. The value of the laboratory test was to confirm the interpretation of some of them, and guiding him in his search for further signs. The value of the duodenal tube had been rather decried that evening, but occasionally it was of definite assistance. It had never been suggested that the injection of magnesium sulphate (25 per cent. solution) directly into the duodenum through the tube was of itself likely to be of great assistance; what it did was to accelerate the bile down into the duodenum. By this method the bile might be brought into the duodenum within ten minutes. The value of the duodenal tube in carcinoma of the head of the pancreas was in showing the absolute absence of bile even after the injection of magnesium sulphate. The value of diastase in acute pancreatitis had been very generally accepted. This reaction might be carried out within half an hour, and therefore it was a test applicable to acute cases.

The discussion concluded with a few remarks in French by Dr. A. MATTHIEU DE FOSSEY of Vichy. Dr. de Fossey emphasized the importance of relying upon the findings of several tests, and not of one only, and especially the importance of blood tests in preference to urinary tests.

## SPASTIC PARALYSIS.

A MEETING of the Orthopaedic Section of the Royal Society of Medicine was held on March 6th, with Mr. T. H. OPENSHAW in the chair. Mr. A. S. BLUNDELL BANKART read a paper on the operative treatment of spastic paralysis.

Mr. BANKART said that spastic paralysis was due to a permanent defect of the upper motor neurone. Such defects were the cerebral palsies of children, resulting in diplegias, hemiplegias, paraplegias, and monoplegias. The condition was essentially incurable. Treatment must be symptomatic, and directed to the relief of contractures. Of these perhaps the most important were plantar flexion of the foot (spastic equinus), flexion of the knee, adduction of the thigh, pronation of the forearm, and flexion of the wrist. It should not be forgotten that spastic paralysis was often accompanied by mental deficiency, motor weakness, or involuntary movements; and these had an important bearing on prognosis and treatment.

The nature of the spastic contracture was a tonic spinal reflex. Fortunately secondary anatomical or structural shortening usually occurred late. The treatment for such muscular shortening was by a direct attack on the shortened muscle. There were several methods of operative treatment for the physiological contractures, which were now under discussion. Non-operative treatment was useless. Forster by posterior root section attacked the afferent side of the reflex arc. Mr. Bankart believed the results by this procedure were generally disappointing, perhaps because the contractures were local, and it was impossible to localize the effects of posterior root section. Again, orthopaedic surgeons could attempt to diminish the effective action of the preponderating muscle group through either muscle or nerve. This was an attack on the efferent side of the reflex arc. The older orthopaedic methods included such operations as division or excision of portions of the adductors, division or excision of portions of the hamstrings, and lengthening of the tendo Achillis. These were all needlessly complicated. There was a tendency for the contracture to recur, and there was the terribly long convalescence during which instruments had to be used.

Much simpler was Stöffel's operation of dividing fibres of the peripheral nerves. This abolished excessive muscular contraction by diminishing the number of muscle fibres taking part in the contraction. Amongst such typical operations might be cited those for adduction contracture, for flexion contracture of the knee, for spastic equinus, and

for pronation-flexion contracture of the forearm and wrist, whilst atypical operations of the same type were those for flexion spasm of the toes, for peroneal spasm, and for internal rotation of the thigh. The result of such nerve destruction was immediate and permanent flaccid paralysis of the muscle fibres involved. There was no tendency for these fibres to shorten; rather they tended to stretch. There was therefore no recurrence of the contracture, and no need for splint, ment, abduction frames or splints, and the instruments so commonly seen were avoided.

In considering the end-results of Stössel's operation, it should be remembered that spasticity was but one of the disabilities of cerebral paralysis. Treatment was necessarily limited, but by this method these terribly handicapped little ones could at any rate be made to walk, although imperfectly. In conclusion, Mr. Bankart said that Stössel's operation was by far the best method yet devised for the treatment of pure spastic contracture. The operation was easy of performance, it was easily adjusted to individual cases, and the results were immediate and permanent.

Mr. LAMING EVANS considered adductor spasm well treated by division of the obturator nerve. He asked: Should one or both branches be divided?

Mr. FAIRBANK thought that it was very necessary to select the operation. If, for instance, in equinus there was real shortening of the calf muscles, Stössel's operation was unsuitable. Elongation of the tendo Achillis was necessary. In flexion contracture of the knee the method was admissible. He agreed that Foerster's operation gave very poor results.

Mr. BRISTOW believed that division of the obturator nerve was admissible for adductor spasm. The question of the whole or partial division of the nerve was not important, since the adductor magnus would still be acting.

Mr. ELMSLIE stressed the necessity for certain diagnosis. Congenital syphilis often simulated spastic paralysis. He always had a Wassermann reaction taken before operating. Afterwards re education was very necessary.

The PRESIDENT remarked that in ordinary hemiplegia there was a limitation of supination of the forearm and of rotation of the arm outwards. He was accustomed to divide the pronator radii teres muscle and the subscapular muscle, with excellent results.

## MENSTRUATION AND PREGNANCY IN HODGKIN'S DISEASE.

A MEETING of the Liverpool Medical Institution was held on March 1st, with the President, Professor J. HILL ADAMS, in the chair, when Dr. ARTHUR GEMMELL read a note on menstruation and pregnancy in Hodgkin's disease.

Dr. Gemmell described a case of Hodgkin's disease commencing in the second month of the second pregnancy of a young married woman, aged 23, who came under notice in 1919.

The diagnosis was established by pathological examination of one of the glands, and treatment with arsenic and extract of lymphatic gland, with the application of x rays to the site of glandular enlargement, was commenced and continued throughout pregnancy. The labour and puerperium were normal. Under further treatment all traces of glandular involvement disappeared. A third pregnancy commenced in 1920 and the glands began to enlarge at the eighth week. The patient then contracted influenza and aborted. Treatment as before caused complete disappearance of the swellings in a few weeks. Her fourth gestation began in the spring of 1922 and the glands enlarged when she was about eighteen weeks pregnant, but treatment as before kept the disease in check, and she had a normal labour and puerperium with a healthy living child.

Little had been written on the relationship of Hodgkin's disease to menstruation and pregnancy. A collection was made of 57 cases in the female from the Liverpool hospitals and the literature. In 17 cases between puberty and the menopause whose menstrual history was obtained, 14 showed varying degrees of oligomenorrhoea of varying degrees even up to complete amenorrhoea, and 3 were unchanged. Of the 10 definitely parous women, 6 dated the onset of their disease from a pregnancy. Twenty-five cases of the series (43.8 per cent.) had their onset in periods of physiological amenorrhoea. Considering the abore with the well known opinion that women were less liable to the disease than men, it was suggested that it was the ovarian hormone which conferred this relative immunity on women and that they only contracted the disease when there was a hypofunction of the ovary as regards its internal secretion. This hypofunction might be true, as before puberty or after the menopause, or relative, as

during pregnancy. The corollary to this suggestion was that ovarian extract should be given in addition to the treatment already mentioned. *Post-mortem* notes on the genitalia were only available in four cases and these supported that view. Notes on the labours and puerperia were available only in six cases. These showed that, on the whole, labours were normal with a tendency to *post-partum* haemorrhage; but three of the patients died within three months of labour. No abortions were definitely attributable to the disease. It appeared that where early Hodgkin's disease and early pregnancy occurred together the uterus should be emptied and the woman warned of the danger of future pregnancies. Dr. Gemmell drew the following conclusions: (1) Possibly Hodgkin's disease occurred, in the female, when there was a hypofunction of the ovary. (2) Diminution in the menstrual flow was a symptom of Hodgkin's disease. (3) Where early Hodgkin's disease and early pregnancy occurred together, the pregnancy should be terminated.

### Osteitis Deformans.

Dr. WALLACE JONES read a note on a case of osteitis deformans, of which Dr. THURSTAN HOLLAND showed radiographs. The case was that of a man who commenced four years ago with pain in legs and muscular weakness, which was thought to follow a slight accident to the hip. There was no family history of similar disease. He had lost two inches in height, and the size of his hat had increased from 6½ to 7¼ inches. He had a hunchback appearance with kyphosis and marked bowing of both tibiae. The movements of both hip-joints were limited. The arteries were thickened. Dr. Thurstan Holland showed a series of lantern slides showing the condition of various bones, including the skull. These showed the typical changes in the x-ray appearances caused by the various degrees of the combined rarefying and proliferation.

### Oxycephaly.

Dr. HENRY COHEN read a note on oxycephaly, illustrating the characteristic features of the condition by photographs and radiograms of three cases which had come under his observation. He emphasized the pressure origin of the so-called "digital markings" by comparing them with the appearances seen in hydrocephalus and brain tumour. In addition to the usual eye signs, congenital cataract was present in a case of scaphocephaly. Dr. NORMAN CAPON believed that the convolutional impressions were due to disordered bone development rather than to pressure. Somewhat similar impressions were found, in craniotabes, and when they occurred in hydrocephalus it was to be expected that the small volume of liquid lying between the external surface of the brain and the internal surface of the cranial bones would nullify direct pressure as the cause.

### Appendicitis.

Mr. ROBERT KENSON read a paper on appendicitis as a possible epidemic disease. In support of this he urged that whereas the yearly mortality in the Liverpool Royal Infirmary for the past five years had averaged 6.2 per cent. for acute cases, a study of the monthly admissions showed more cases admitted from May to October, and while periods of six months might elapse without a death, on four occasions the monthly mortality reached 33 per cent. Cases admitted in 1921 were greater in number, of greater pathological virulence (abscess formation 56 per cent. against 33 per cent. in other years), and had a higher mortality, especially in the month of June. The mortality curves and incidence curves of hospital and general practice bore no relation to influenza, but followed other streptococcal diseases such as rheumatic fever, erysipelas and puerperal fever, less so scarlet fever. Liverpool had a lower death rate from appendicitis than Manchester, Birmingham, and Leeds, when the population was considered.

## GYNAECOLOGICAL CASES AND SPECIMENS.

A MEETING of the North of England Obstetrical and Gynaecological Society was held in the Liverpool Medical Institution on February 16th, with Professor W. BLAIR BELL in the chair, when a number of specimens were shown and interesting cases recorded and discussed.

Drs. LEITH MURRAY and MEREDITH LITTLE presented a final report on their case of "mixed tumour" of the uterus (adenocarcinoma), reported in full in the *Journal of Obstetrics and Gynaecology of the British Empire* in January, 1914. The patient, more than nine years after operation, was alive and well.

Drs. RUTH NICHOLSON and PICKERING JONES showed a 38-weeks female foetus with numerous abnormalities—achondroplasia, general oedema and ascites, transposition of viscera, supernumerary spleniculi and digits, dilatation of ureters, and under-developed ovaries. The histological appearances in the liver, etc., suggested the further condition of leukaemia. Dr. N. B. CAPON pointed out that the changes suggestive of leukaemia were commonly found in foetuses with oedema and ascites, and were probably associated therewith.

Dr. J. H. WILLETT showed a specimen of repeated ectopic gestation with intraperitoneal rupture.

Nine years ago the patient was operated upon for perforated gastric ulcer; pelvic stab drainage was required and she was in hospital for twelve weeks. Five years ago Dr. Willett operated for right-sided ectopic gestation and removed the tube; dense adhesions were found in the pelvis, the left tube was freed, found healthy, and conserved. Menstrual regularity followed until September 29th, 1922; on November 10th there was a slight bleeding, and on the 27th an abdominal crisis, from which the patient rallied. The abdomen was reopened on December 1st, and a ruptured ampullary gestation was found on the left side; the embryo, placenta, and clots were free in the pelvis, and salpingectomy was performed. Dr. Willett considered that the pelvic adhesions were the probable cause of kinking of the tube and arrest of the ovum. He pointed out the rarity of primary intraperitoneal rupture of ampullary gestations and suggested blocking of the abdominal ostium had occurred with resulting increased tension.

Dr. D. DOUGAL showed an adenomyoma of the vermiform appendix, the tip of which was coiled and adherent in the pelvis near to, but not in contact with, the right ovary. Typical endometrium was found in the wall of the appendix; the section of ovary examined was suggestive of adenomyoma.

Professor H. BRIGGS showed a case of fibroid which emphasized the value of Péan's work.

The vaginal route was demanded by a low-lying tumour and a weak pelvic floor, the removal of the one and the restoration of the other being effected within a single field of operation with the maximum of safety. The tumour, the uterus, and the appendages (bilateral hydrosalpinx) weighed 1½ lb.; weight and size indicated a piecemeal removal (Péan) or Professor Briggs's own alternative (published in 1893), of cutting the tumour into a connected, chain-like column, easily brought down. Free cutting into a fibroid drained away blood and serum and reduced the average total weight by one-fifth.

Miss IVENS showed a submucous fibromyoma removed by myomectomy.

A solitary fibroid in the anterior uterine wall in a young woman aged 22 was a condition which appealed strongly for conservative treatment. The patient had a history of six weeks' profuse irregular haemorrhages, with clots and abdominal pain; a tender smooth swelling, the size of an orange, was continuous with the cervix. The tumour with the subjacent mucosa was removed through an anterior vertical incision; careful suture of the musculature brought the mucosa into close apposition not requiring separate suture. A year later the patient was in good health. On section the tumour showed necrobiosis and hyaline changes.

Dr. FLETCHER SHAW read the notes of a case of fibromyoma of the cervix occurring after supravaginal hysterectomy and recurring after myomectomy.

The patient had supravaginal hysterectomy done and both appendages removed in 1917, on account of old inflammatory matting of the appendages, probably due to tuberculous trouble. Four years later she came under observation again because of persistent haemorrhage, and a fibroid was then found completely filling the pelvis and presenting at the cervix, which admitted two fingers. This was removed by abdominal myomectomy and the cervix left behind, as it was so adherent to the side of the pelvis that removal would have been an extremely difficult operation. Five months later she returned with another hard mass in the pelvis and this was treated with x rays; after twelve months it had slightly diminished in size, and there had been no haemorrhage for six months. Microscopical examination showed the tumour removed by myomectomy to be a simple fibromyoma, though the early recurrence was suspicious of sarcoma; this, however, was unlikely in view of the slight reduction in size and the cessation of symptoms after x-ray treatment.

Dr. MILES H. PHILLIPS recorded a case of chronic inversion of the uterus which emphasized the value of Aveling's repositors.

A complete inversion of uterus and cervix was discovered four months after the confinement. After the necessary attention to the local toilet, the repositor was introduced and completed its work within twelve hours. Dr. Phillips had had two small holes bored through the head of the repositor to relieve the difficulty previously experienced in removing a repositor with a solid head, owing to suction between it and the uterus. This had been completely satisfactory. He further emphasized the slight pressure required, which was furnished by two rubber "paper bands."

Dr. LEITH MURRAY presented a case of "tarry cysts" of the ovary associated with subperitoneal adenomyoma.

The patient was 42 years of age, and had one child 8½ years old. She had had severe and increasing congestive dysmenorrhoea for five or six years; menses were usually scanty, occasionally profuse. Inflammatory appendage disease was diagnosed because of the fixation of the uterus with enlarged, tender, and somewhat cystic appendages. Operation revealed dense adhesions about the enlarged uterus, and the appendages were removed. These burst during oophorectomy; the bladder was slightly adherent to the anterior wall of the uterus. The uterus was 1½ inches thick at the fundus and 1 inch elsewhere; in the anterior wall, near the fundus and rather to the left of the middle line, was a rounded, pale nodule, half an inch in diameter; this was obvious as soon as the abdomen was opened, and was certainly not adherent to either appendage. It was slightly raised and, on section, had no capsule. This nodule showed microscopically a definite adenomyomatous stroma, was without a capsule, and without any evidence of tuberculous granuloma or of the inclusion of the interstitial part of a Fallopian tube. Definite adenomatous elements of endometrial type were found in each ovary. The endometrium was oedematous and polypoid. Without question there was no direct extension of an adenomatous process from the ovary to the uterus by way of adhesion. Dr. Murray had never before seen a subperitoneal adenoma so definitely situated in the uterine wall. He was tempted to wonder whether too much had not been made of an obvious similarity between the glands and surrounding stroma of extrauterine adenomata and the endometrium proper. A case such as this seemed to lend some basis for Meyer's view that those growths are more correctly entitled "adenomatoses."

### CAUTERIZATION OF PLEURAL ADHESIONS BY THORACOSCOPY.

A MEETING of the Aberdeen Medico-Chirurgical Society was held on March 8th, with the President, Dr. ALEXANDER OGSTON, in the chair, when Dr. JAMES LAWSON (Tor-na-Deo Sanatorium) demonstrated a case of cauterization of pleural adhesions by thoracoscopy, illustrated by skiagrams. The patient suffered from pulmonary tuberculosis affecting practically the whole of the right lung. An artificial pneumothorax was induced on that side, but complete collapse of the lung was prevented by adhesions in the region of the upper lobe and of the diaphragm. The thoracoscope was inserted into the pneumothorax cavity in the sixth space in the scapular line and the adhesions inspected. The upper adhesion was found to be too extensive for cauterization; the lower adhesion was divided by the cautery passed through another cannula inserted in the sixth space in the anterior axillary line, the action of the cautery being controlled by inspection through the thoracoscope. Local anaesthesia only was employed. Following this operation there was a considerable increase in the amount of collapse of the lung, though not so much as would have followed had it been possible to deal with the upper adhesion also. Dr. Lawson described briefly the difficulties of the operation, showed the patient, and demonstrated the instruments required, with skiagrams of the case. A short discussion followed, in which Professor ASHLEY MACKINTOSH, Mr. F. K. SMITH, and the PRESIDENT took part.

#### Parham's Bands.

Mr. F. K. SMITH then gave a short paper, with lantern illustrations, on the treatment of fractures by Parham's bands. Mr. Smith pointed out that any method which reduced the loss of working time in a fracture case was worthy of trial; he indicated the disadvantages of different methods of fixation by open operation, and stated that he had found the following advantages of Parham's method: the ease of application, the comparatively small wound required, the small amount of manipulation necessary, and the better chance of aseptic healing. The cases in which this method had been found most suitable were those of oblique fractures, and often in comminuted fractures. In transverse fractures, bands alone were unsuitable, and should be combined with Sherman's plates. Mr. Smith demonstrated the special instruments used, and showed a series of lantern slides of skiagrams of eight cases before and after operation. In the subsequent discussion, Professor MARNOC, Mr. DOX, Mr. MITCHELL, Dr. ROSE, and the PRESIDENT took part.

#### Statistics of Appendicitis.

Mr. G. H. COLE read a paper on the results of the treatment of cases of acute appendicitis occurring in Professor Marnoch's wards in the Aberdeen Royal Infirmary from January, 1911, to December, 1921. There were 675 cases, of which 568 (84 per cent.) were operated on within twenty-

four hours of admission and 107 were kept under observation; 92 of the latter were subsequently operated on without mortality, a definite lesion of the appendix being found in all of them. The mortality in the 568 cases operated on immediately was 6.3 per cent., but excluding 7 cases of wrong diagnosis, with two deaths (one being a case of volvulus and one a case of small ovarian cyst from which streptococci were isolated), the mortality was 6.07 per cent. In 94 cases without pus the mortality was 1.06 per cent. of those drained, and in 165 cases without pus, not drained, 1.81 per cent. In 170 gangrenous cases the mortality was 8.82 per cent., in 62 perforated cases 11.3 per cent., and in 99 abscess cases 3.03 per cent. The chief conclusions were as follows: (1) About 84 per cent. of acute cases required urgent operation; (2) about 90 per cent. of all cases requiring urgent operation would suffer primary appendicectomy; and (3) when pus appeared in a gangrenous case the risk rose from about 2.4 per cent. to 8.8 per cent., and in some third-day cases to double this, the risk rising geometrically as the time increased arithmetically. Professor MARNOCH and Mr. SMITH contributed to the discussion, and some interesting remarks from the statistical point of view were made by Dr. J. F. TOCHER.

### PNEUMONIA AND ITS COMPLICATIONS.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society on March 1st, with Dr. D. W. LIVINGSTONE, the Vice-President, in the chair, Dr. WALTER BROADBENT read a paper on pneumonia and its complications.

Dr. Broadbent remarked that physical signs might not be evident for a day or two after the onset. In was in those cases that a right-sided pneumonia might be confused with appendicitis (especially if there was some inaudible diaphragmatic pleurisy giving rise to pain and rigidity of the abdominal wall), but respirations would be rapid and breath sounds weaker than normal, and there would be no tenderness per rectum. A low temperature in a case with extensive physical signs usually meant deficient resistance, as also did a rapid or intermittent pulse. In favourable cases there was a marked leucocytosis. He described haemorrhagic and oedematous types of pneumonia, which occurred in influenza epidemics. He advised that pleuritic fluid should not be drawn off till after the fall of the temperature unless there was embarrassment of the heart. Empyema was the most common complication. In children breath sounds could often be heard through pus, so it might be missed. Interlobar empyema was difficult to diagnose as every case differed. There might be dullness in the second and third spaces in front, or at the level of the spine of the scapula behind. There was generally bronchial breathing in the upper lobe and a varying degree of signs of compression of the lower lobe. The best place for operating was in the upper axilla with the arm raised. He had made the diagnosis in five cases, four being cured by operation. Dr. Broadbent described a case of empyema between the mediastinum and the left lung, which was collapsed and adherent to the chest wall. In operating the surgeon removed a portion of the eighth rib just external to its angle. Another case had an empyema between the base of the right lung and the diaphragm, which was found by a dull area three inches broad over the lower ribs in the posterior axillary region. He described a case of suppuration of bronchial glands after a very severe pneumonia. It was characterized by spasmodic cough lasting for hours, by dullness in the second right space and under the sternum, and by displacement of the heart to the left. Recovery took place after the sudden coughing up of half an ounce or more of pus. Ulcerative endocarditis might be set up by the pneumococcus; one such case with pyrexia, showers of small emboli in the lower legs and forearms, occasional infarcts in the lungs, and intermittent albuminuria had been cured by Dr. Helen Boyle and himself by numerous injections of antipneumococcal serum continued in spite of severe anaphylaxis. Meningitis occurred mostly in young children. It was usually fatal, but he had had two cures by daily lumbar puncture, frequent injections of serum, and large doses of urotropin. In one of them the cerebro-spinal fluid resembled empyema pus.

In regard to treatment he was strongly of opinion that the patient should be moved as little as possible by nurses, since auto-inoculation occurred so readily. For lobar pneumonia with high temperature he thought the ice-bag good. Vaccines, if of the right type of pneumococcus, were useful if given on

the first or second day. In delayed resolution and after empyema autogenous vaccines hastened cure. He had excellent results from the use of the Pasteur Institute anti-pneumococcal serum, and also from Pane's serum. Medicinally he thought aspirin and quinine valuable, also the creosote and potassium iodide mixture, and for extremely poisoned cases Warburg's tincture. If the pulse rate was up to 100 digitalis should be given, and if up to 120 hypodermic injections of strophanthin; camphor hypodermically was valuable.

### Nerve Implantation in Facial Paralysis.

Mr. H. F. SEYMOUR then showed a case of facial-hypoglossal implantation for facial paralysis.

He said that a boy, aged 11, had been treated for chronic otitis media of long standing of the right side for about a month without success. A radical mastoid operation was then performed. Facial paralysis came on three days later (although the facial nerve had not been injured) and did not take place even after five months of electrical treatment. An implantation of the hypoglossal nerve was then undertaken. The operation was difficult, there being some enlarged lymphatic glands just below the tip of the mastoid process. In clearing these out the nerve was found to be bound up in the connective tissue of the periosteum, as it came out of the stylo-mastoid foramen. Consequently the trunk of the nerve had to be found at the entry of the parotid gland, where it was completely divided. Having dissected it out and isolated the hypoglossal, a nick was made into the latter and the facial trunk drawn by fine catgut sutures into the former. Assured of no undue tension, the junction was buried in the posterior belly of the digastric muscle. Five months passed before any recovery was noticed, the patient then beginning to use the risorius muscle, the levator labii superioris and orbicularis oris coming into action once more. The eye was shown to shut quite well, but the frontal portion of the occipito-frontalis was still paralysed, and there was no sense of taste on the right-hand side of the tongue anteriorly from permanent destruction of the chorda tympani branch on this side. The tongue moved normally and the movements were daily improving, and the expression of the face on smiling was practically normal. Mr. Seymour discussed the advantages of using the hypoglossal nerve for this purpose instead of the spinal accessory.

### ELEVATION OF THE DIAPHRAGM DUE TO UNILATERAL PHRENIC PARALYSIS.

At a meeting of the Röntgen Society on March 6th, Sir HUMPHRY ROLLESTON presiding, a paper was read by Dr. J. M. WOODBURN MORISON of Manchester on the elevation of the diaphragm and its connexion with unilateral phrenic paralysis.

Dr. Woodburn Morison said that certain forms of congenital elevation of the diaphragm were probably due to a unilateral phrenic paralysis, and he proceeded to give a radiological study of a number of cases. It was not uncommon, he said, for paralysis of the diaphragm to be caused by a definite lesion involving the phrenic nerve in its passage through the thorax, although little was to be found on the subject in radiological literature. In nine cases he discovered paralysis of either the left or right leaflet of the diaphragm, variously associated with secondary carcinoma, primary growth in the chest, tuberculosis, and aneurysm of the aorta. In all these cases the diaphragmatic movements on the affected side were reversed, and in two cases he was able to obtain post-mortem evidence to confirm the diagnosis of unilateral phrenic paralysis. He was convinced that when the phrenic nerve was paralysed the movements of the affected leaflet must be reversed unless the diaphragmatic movement were impeded altogether by reason of a new growth; and there was some evidence, which he recounted, in support of the theory that these cases were due to an injury of the phrenic nerve at birth which had remained for a long time latent.

Sir HUMPHRY ROLLESTON said that Dr. Morison had correlated three groups of cases. The first group consisted of the cases which were known as Petit's eventration, or which used to be spoken of as congenital or false diaphragmatic hernia. The question in his own mind had been as to whether these cases were not due to a congenital atrophy of the muscular fibre of the diaphragm, which might remain latent throughout life unless some such event as a stricture or twisting of the stomach took place. Dr. Morison had put forward the view that there was a definite cause for the atrophy of the diaphragm occurring very early in life, and it was certainly a remarkable fact that this congenital or false diaphragmatic hernia was so very much more common on the

left than on the right. The other two groups were those in which there was an injury or wound giving rise to the hernia, and those in which there was a definite paralysis of the phrenic nerve on one side.

Sir CHARLTON BRISCOE agreed that paralysis of the phrenic nerve was common. He had seen four cases post-mortem in which the diaphragm was definitely paralysed and the phrenic nerve destroyed. These were cases mostly of new growths in the chest, and almost always on the left side. This condition was frequently missed in examinations during life because of the presence of fluid, and it was generally missed in the post-mortem room because trouble was not taken to dissect out the nerves, and the degenerated muscle showed very little difference from the normal muscle, often only a rather more brownish tinge and a lessened elasticity to the touch. There were no physical signs by which the paralysis of one-half of the diaphragm could be detected. It might be suspected very strongly, but there were no true physical signs, no alteration in the size of the chest, or of necessary muscular movements. Therefore the x-ray picture was of enormous value. There was one little sign in cases of paralysis of the left half of the diaphragm which was worth noting—namely, that at the end of inspiration there was a little tug of the mediastinum to the right. That seemed to be of great value when the general picture was obscured by fluid.

Sir ARCHIBALD REID said that he had one case in which what was almost certainly a congenital hernia was only discovered—by radiological means—when the patient was 40 years of age. The patient, who had had very acute symptoms for a short period, had been completely comfortable ever since the discovery of the anomaly.

Dr. ROBERT KNOX described a case in which a patient had a left-sided pleural effusion to begin with, and then suddenly developed marked dullness on the right side. On screen examination the diaphragm on the right side was observed to be at a high level. Later a tumour was discovered, which cleared up under x ray treatment, and with the clearing up of the tumour and the relief of the pressure the diaphragm recovered its normal movement.

### ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A MEETING of the Royal Medico-Chirurgical Society of Glasgow was held on March 2nd. Dr. JAMES ADAM showed a case of laryngectomy done under local anaesthesia, and discussed shortly the question of anaesthesia in relation to operative mortality. Dr. Adam pointed out that shock, septic pneumonia, and mediastinitis are the three most important dangers to be guarded against in these operations. Continental surgeons have shown that these dangers are best guarded against by local rather than general anaesthesia; Dr. Adam described the operation performed successfully upon his patient, and demonstrated the result and the specimen.

Dr. W. S. SYME made a communication on surgical diathermy in the treatment of malignant disease of the throat, and showed several patients. One of these demonstrated the type of case treated and others the results obtained. Dr. Syme explained the procedure and detailed his operation in each case. The treatment was employed at first only for inoperable cases, but as experience of its use had enlarged it was being more and more recognized as applicable and preferable to the ordinary procedures for cases of malignant disease of the mouth and especially of the pharynx in all stages. The advantages appeared to be the following: The operation was practically bloodless, and no external operation was required to expose the growth in the majority of cases. Patients, too, recovered rapidly, even after a large removal.

Dr. G. H. STEVENSON made a communication on tendon transplantation for musculo-spiral paralysis, and showed patients. He discussed the relative values of nerve suture and tendon transplantation in a small group of wounded soldiers in the West of Scotland, and concluded that for rapidity of restoration of function the latter operation had points rendering it preferable to the former. He described the operation performed where certain of the flexor tendons were transplanted into extensor tendons sufficient to carry out ordinary movements of extension. Lastly, Dr. Stevenson explained the difficulties of after-treatment, showing simple splints devised to facilitate recovery of function, and showed several patients who had been treated by his method with remarkable results.

## Reviews.

### AN EDWARD NETTLESHIP MEMORIAL VOLUME.

THE one branch of medical science wherein the importance of hereditary studies has been fully appreciated, and wherein splendid work has been done during the last decade, is undoubtedly ophthalmology, and none can hesitate to admit that the main incentive was the inspiration provided by Edward Nettleship. The editor of the *Treasury of Human Inheritance*,<sup>1</sup> Professor Karl Pearson, who made a joint inquiry with Nettleship into albinism, came to the conclusion that Nettleship would himself have preferred as a memorial a record of work done by others as well as by himself. Professor Pearson has accordingly prepared a Nettleship Memorial Volume of the *Treasury* containing Nettleship's own work, that of his immediate students and friends, and that of other ophthalmologists who have contributed to the knowledge of hereditary diseases and anomalies of the eye.

The first part of the volume contains an account of the life of Nettleship written by Mr. J. B. LAWSON, who had the privilege of a long and close association with Nettleship, and who confesses to "an unbounded admiration for the true nobility of his character and a deep appreciation of his warm-hearted and sympathetic nature." Nettleship was born in the country of a father who had been both a rector and a head master, and was a man of considerable intellectual power with a developed taste for poetry and music; and a mother who was noted for her vigour of character. Of his several brothers three besides himself became noted in their spheres of work. Although as a boy Nettleship's love of outdoor life marked him out for a farmer, he became a veterinary surgeon and a professor of veterinary surgery at Cirencester College. But he speedily became a Member and then a Fellow of the Royal College of Surgeons of England. At the London Hospital he worked for Jonathan Hutchinson and received an impress from that diligent investigator that remained with him for life. His bent was early to ophthalmology, and being attached as a student to Moorfields Eye Hospital, he became curator of the museum, and, after a period at the Royal Eye Hospital, a member of the surgical staff at Moorfields; and also the ophthalmic surgeon at St. Thomas's Hospital in succession to Liebreich. His diligence and method made his work successful whether as a hospital surgeon, as Dean of his school, as investigator of the eye conditions of the children at Poor Law schools, or in private practice. But at the height of his professional success he retired to Hindhead and devoted his time and energy to the study of heredity in disease. During the ten years that followed he accomplished a prodigious amount of work of a very high standard, "working in such a way that his researches are models of orderly observation and recording." He was elected F.R.S. in 1912 and the esteem and regard of his pupils was expressed by their collection of a fund which by his desire was devoted to the establishment of a medal "for the encouragement of scientific and ophthalmic work."

He was known to his brothers as "Bird-bearing Ned" on account of his devotion to natural history and particularly to bird life, and his love of Nature found full play in his home at Hindhead, in his garden and in the woods, with the birds, trees, and flowers of that beautiful spot. In the country he was born, in the country he loved to work, and in the country he died.

The main part of the volume is devoted to the consideration of retinitis pigmentosa and allied diseases. It is now well recognized that retinitis pigmentosa itself is a developmental defect, the exact nature of which is obscure. In congenital stationary night-blindness the case is different; both types of this condition are undoubtedly due to some congenital developmental defect, but nothing is known of the nature of the defect, and there is no reason other than convenience for grouping together the diseases which have the common symptom of night-blindness. A search in the works of early writers has failed to reveal anything more suggestive of the existence of this disease than the statement that night-blindness did not always respond to treatment and that it

<sup>1</sup> The *Treasury of Human Inheritance*. Eugenics Laboratory Memoirs, XXI. Francis Galton Laboratory for National Eugenics, London. Volume II: *Anomalies and Disease of the Eye* (Nettleship Memorial Volume). Part I: *Retinitis Pigmentosa and Allied Diseases*; *Congenital Stationary Night-Blindness*; *Albinism*. By Julia Bell, M.A., M.R.C.S., L.R.C.P., with a Memoir of Edward Nettleship by J. B. Lawson, LL.D., F.R.C.S. Cambridge University Press, 1922. (12s. net.)

might progress to the complete loss of sight. But the symptom of night-blindness has been recognized by writers of all ages in all countries, associated with many forms of malnutrition and exhaustion disease, and there was a common tendency to rely on the virtues of liver as a specific; a prescription for it as early as 1500 B.C. has been discovered in the famous "Book of the Eyes" found in the Theban Necropolis. Whether temporary night-blindness has any relation to the severer progressive retinitis pigmentosa, or whether normal members of stocks that suffer from the congenital defects are more liable than others to temporary affections, is a speculation of interest. The first certain record of hereditary disease is due to Orelgün in 1744, but nothing more is found until 1830, when Richter described the affection in three of a sibship. Eight years later Cunier gave the famous Nougaret pedigree of six generations—a pedigree which was brought up to ten generations by Nettleship, who himself examined certain members of the family and showed that the affection was congenital night-blindness, and not retinitis pigmentosa. Pigmentation of the retina had been seen *post mortem* by Langenbeck in 1836, but the appearance was not correlated to night-blindness until seen by the ophthalmoscope. That instrument completely revolutionized the work of the ophthalmologist, though it is sad to have to admit that, so far as this group of disease is concerned, the benefit of the discovery is limited to the ophthalmologist and has contributed nothing to the relief of the patient.

Since cure is not to be expected, prevention becomes all important, and therein lies the value of the knowledge of the conditions of inheritance. The signs and symptoms of the disease are very clearly and accurately set out in the pages of the volume, with citations of the writings of those who have contributed to our knowledge. Statistics are given of the known age of onset and the rate of progress of the limitation of sight. It may be accepted that the onset is at an early age in the great majority of cases, and is a rare occurrence after the age of 20 years; also it may be accepted that sight is very frequently lost before the age of 40 years. Opinion has for some time been almost unanimous that the disease should be regarded as of an atrophic or degenerative nature, but opinion is by no means agreed as to whether the degenerative process originates in the chorio-capillaris, the layer of the choroid which is entirely responsible for the nutrition of the outer layers of the retina; whether it originates in the nervous elements of the retina itself, manifesting first in the layer of rods and cones; or whether some defect of the retinal vessels precedes the degeneration of the nervous elements of the retina. Nettleship held the view that the chorio-capillaris was at fault, but recently some evidence has been given that the primary atrophy is of the retinal elements. No hypothesis seems to satisfy all conditions entirely, and many a "beautiful theory has been killed by a nasty little fact." In most forms of hereditary congenital defect it is common to find many associated defects. These are not common with retinitis pigmentosa; only two are found with any frequency—namely, deafness, often deaf-mutism, and idiocy or some type of mental defect or defect of the central nervous system. The condition occurs more or less uniformly in European countries; it is perhaps less frequent in America, and rare amongst negroes. It is said to be common in China, but not on very reliable evidence, and it is common in India. Consanguinity appears to have some influence, for with an increase in the percentage of consanguinity there appears to be an increase in the defect resulting. The male tends to become affected more readily than the female, but is less liable to transmit the disease to his offspring.

The section dealing with congenital stationary night-blindness illustrates the incompleteness of our knowledge of this rarer condition; indeed, it is by no means certain that the defect is in the eye at all, for so far it has not been found possible to make a microscopic examination of the eye of an affected person.

A most complete bibliography of the disease is provided, together with details of some 300 pedigrees, each illustrated by charts drawn on the a plan uniform with the Galton Laboratory system. It would be invidious to distinguish any part of the work more than another, yet some appreciation may be permitted of the fine collection of pedigrees by Usher of Aberdeen, who was one of Nettleship's most enthusiastic colleagues in the prosecution of this work.

Finally, there is a section dealing with that destructive form of eye disease known as glioma retinae. A new growth of the retina which occurs exclusively in very young children

and is malignant in that it infiltrates surrounding tissues may extend by proliferation of the primary growth by continuity along the optic nerve to the brain or may be widely disseminated by means of the lymph channels or blood stream forming metastases in the glands, bones, or occasionally distant organs of the body. Thirty-six small family histories have been collected, giving records of 128 cases. There is no evidence of correlated defects of other kinds; consanguinity is not evident, and the data are insufficient to indicate any sex liability. But there is sufficient evidence of liability to hereditary continuance of the disease "to raise grave doubts as to whether any member of a sibship in which more than one member is affected ought to marry."

The whole work is prepared with the unsurpassable accuracy which marks all the productions of Professor Karl Pearson's laboratory, and the printing and make-up of the volume is a good example of the work of the University Press of Cambridge.

### SYPHILIS OF THE INNOCENT.

*Syphilis of the Innocent*,<sup>2</sup> by Dr. HARRY C. SOLOMON and MAIDA HERMAN SOLOMON, is mainly concerned with the social side of this complicated and very important subject, though the purely medical aspects are by no means neglected. It is not the first book that has been written under the same or a similar title, for we have Bulkley's *Syphilis in the Innocent*, Fournier's *La Syphilis des Honnêtes Femmes*, and Scherer's *Die Syphilis der Unschuldigen*. But no other title, so accurate and so expressive, could have been chosen. Of the three forms of innocent syphilis—conjugal syphilis acquired by the mate, congenital syphilis in the children, and extragenital syphilis—the first two, constituting genital innocent syphilis, have always been far the most numerous, and as yet there is little evidence that their number is diminishing; while the cases of extragenital syphilis have certainly decreased. The problem of extragenital syphilis as regards control and prevention is simple compared with that of innocent syphilis in the mate and children of a syphilitic marriage. And although all three divisions of innocent syphilis are dealt with in this volume, the authors devote much more space to the extraordinarily complicated subject of syphilis acquired by the spouse (in most cases the wife) and transmitted to the children. On this, nothing more striking, terse, and true has been said than Dechambre's words, that "syphilis is divided among husband and wife like the daily bread." The authors have done well to recover this French epigram, which indeed is so good as to deserve a place on the title-page of their second edition.

The plan of the book is clearly seen from the chapter headings, dealing with syphilis in the individual, the mate, the child, the family, and the community. Statistics from the large clinical material of the authors and from many other clinics in America and Europe are presented and compared, and the very numerous points raised are illustrated by 152 short records of cases. These clinical records bear the name and surname of the patient, but it is explained in a footnote, which might easily escape notice, that these names are fictitious and are given apparently to add colour to the narrative. These records certainly relieve and illuminate the tediousness of figures and percentages. The comparison is chiefly between Fournier's French statistics and those of various American clinics. Of syphilitic women, about 80 per cent. are married, and of these married women 75 per cent. have acquired it from the husband in Fournier's figures, while American statistics show a lower figure of 50 per cent. or less. It appears that the risks to the woman are much greater earlier than later in marriage, 86 per cent. of women acquiring syphilis from their husbands in the first year of marriage (Fournier). The authors present a study of the families of 555 syphilitic individuals, the majority of them in a late stage of the disease; out of these the Wassermann test was done in the mates in 336 cases (these were mostly women), and was positive in 30 per cent. and negative in 68 per cent. A very careful examination has been made of the children of these 555 syphilitic marriages; the percentage of barren marriages (30 per cent.), the percentage of living children giving a positive Wassermann test (8 to 16 per cent.), and the percentage of syphilitic pregnancies, including miscarriages and stillbirths (50 per

<sup>2</sup> *Syphilis of the Innocent: A Study of the Social Effects of Syphilis on the Family and the Community. With 15 Illustrative Cases.* By HARRY C. SOLOMON, B.S., M.D., and MAIDA HERMAN SOLOMON, A.B., B.S. Washington: United States Interdepartmental Social Hygienic Board. 1922. (Med. Soc., pp. iv + 239.)

cent.), are a few of the more important results. An excellent summary of this familial inquiry is given on page 128; and from it one curious and perhaps unexpected conclusion may be quoted: "One-fifth of all children born alive in syphilitic families were dead at the time the families were examined. This does not differ materially from the general average in the community." If this is correct, it means that the effect of syphilis on the child is much more deadly before than after birth; and that syphilitic children born alive have as great a chance of survival as healthy children. With regard to the question of when a syphilitic may safely marry, the authors take the old conservative view of a period of prolonged thorough treatment followed by a period of strict medical supervision without treatment; if these conditions are fulfilled, they would permit marriage although the Wassermann test is positive. As for the children of a syphilitic marriage, they do not recommend specific treatment in the absence of the stigmata and symptoms of congenital syphilis; and in this are not in agreement with some modern authorities. They emphasize the contagiousness of congenital syphilis in the florid stages, but its non-contagious nature in the later stages; and they do not believe in the transmission of congenital syphilis to another generation.

The clinical aspects of innocent syphilis receive less but still adequate attention. We regret perhaps the table of symptoms of congenital syphilis given on page 58,<sup>3</sup> which includes almost every condition that anybody has considered syphilitic, even pyloric stenosis. Such a table gives little help, and may very well be positively misleading. It would, however, be unfair to dwell on the small faults of a really admirable book. It covers a large and very intricate subject in the small compass of two hundred pages, and its style is distinguished by brevity, clearness, and a singular absence of exaggeration of statement.

#### SOME ACUTE INFECTIOUS DISEASES.

Dr. H. BARBIER's little work on mumps, whooping-cough, influenza, and erysipelas<sup>4</sup> is one of the volumes belonging to the *Encyclopédie Scientifique*, published under the editorship of Dr. Toulouse. The relative importance of the four diseases dealt with in this book is shown by 38 pages being allotted to mumps, 85 to whooping-cough, 100 to influenza, and 65 to erysipelas, including a special section on erysipelas in the newborn. An excellent account is given of each of these diseases, due consideration being paid to the history and epidemiology as well as to the pathology, symptomatology, and treatment. In dealing with the frequency of mumps, orchitis, and the subsequent testicular atrophy the writer quotes Laveran's statistics, the accuracy of which Bénard has recently disputed in a paper based on a study of 400 personal cases of mumps, the statistics of various writers, and the statistics of the French Army for the last twenty-one years amounting in all to 200,000 cases. The frequency of mumps orchitis, which Laveran estimated to be 33 per cent., is, according to Bénard, only 17 per cent., and the frequency of testicular atrophy, estimated by Laveran to be about 70 per cent. of the cases of orchitis, is, according to Bénard, not higher than 50 per cent. Dr. Barbier does not share in the enthusiasm of some of his compatriots who regard subcutaneous injection of ether as almost a specific for whooping-cough; he finds its results inconstant, and he briefly dismisses sodium benzoate, recently advocated by American writers, as "not to be recommended." The basis of his treatment consists in administration of oxymel scillae for five days alternately with a preparation containing grindelia, belladonna, and valerian. He condemns the nursing of cases of whooping-cough in the same ward, even if the simple cases are in one ward and the complicated in another, and is strongly in favour of individual isolation of each case in a cubicle, one ward being reserved for cubicles containing simple cases, and another ward for the complicated cases. A counsel of perfection, which he admits is impracticable, is that the staff attending one ward should never come into contact with the staff of the other for meals, distribution of linen, or any purpose whatsoever. In the article on influenza, though a few lines are devoted to the prophylactic use of vaccines, all that is said of vaccine therapy is that it has proved ineffective, nor is any account given of the treatment of influenza by injection of convalescent serum, which has proved valuable in influenzal pneumonia. Dr. Barbier is sceptical about the value of many of the local applications

recommended as well as about the utility of serum treatment in erysipelas. Frequent applications of warm compresses or pads of wool soaked in alcohol and covered with mackintosh he regards as sufficient. A bibliography is appended, in which we can find little more than half a dozen British names among nearly three hundred authorities quoted.

Although this volume, like the majority of French textbooks, unfortunately does not contain an index, the fullness of its table of contents serves to some extent to remedy this defect.

#### ORTHOPAEDICS IN GENERAL PRACTICE.

Dr. PRIVAT's book on orthopaedics in general practice<sup>5</sup> forms one of the Series Comment Guérir (How to Cure), and its avowed aim is to enable the general practitioner to make early diagnosis, give an accurate prognosis to the friends, and carry out the treatment to as successful a conclusion as is possible. Therefore the author has restricted himself to the usual run of orthopaedic cases, and has not attempted to discuss rarities or disputed points in pathology or treatment. Assuming that his readers have no special knowledge, Dr. Privat rightly goes minutely into every small detail of the technique which must be followed in the application of plaster-of-Paris and other supports and corrective apparatus.

Beginning by laying stress on the importance of immobilization in the treatment of surgical tuberculosis and some other conditions, the author defines contractions of joints, and describes ingenious and simple methods by which the patient can carry out passive movements. The next two hundred pages are taken up by directions for the application and the care of plaster-of-Paris appliances. The advice given is practical and based upon good principles. We think, however, that the excellent shears of Stille for the removal of plaster should have been mentioned as a labour-saving instrument of great value.

In another 270 pages the treatment of surgical tuberculosis and some other infections is dealt with on conservative orthopaedic lines, with which open-air hospitals have made us familiar in this country as well as abroad. For injection of abscesses after aspiration Dr. Privat uses a mixture of olive oil, ether, creosote, guaiacol, and iodoform, but he does not attach very great importance to the composition of this fluid. In cases of inspissation of pus in chronic abscess he recommends a liquefying injection. Methods of correcting ankylosis in bad functional position are recommended and described.

The third part of the book treats of congenital affections, such as wry-neck, dislocation of hip, and club-foot. The fourth part, on infantile paralysis, is very short and inadequate and suggests a small experience of this class of deformity on the author's part. The section on apparatus for palsy of various nerve trunks contains some useful hints. A good deal of space is given to the treatment of scoliosis by active and passive exercises, but this chapter and the short ones on rickets, coxa vara and flat-foot, call for no remark.

From the foregoing it will be gathered that Dr. Privat takes a somewhat restricted view of orthopaedic practice. Although very occasionally he recommends cutting operations he does not describe any, and he ignores the orthopaedic treatment of injuries of bones and joints. Like so many Continental surgeons, he appears never to have heard of Thomas's knee and hip splints.

#### DUFF HOUSE PAPERS.

The volume *Duff House Papers*<sup>6</sup> is a series of articles on diagnosis and treatment, written for the most part by members of the staff of Duff House and edited by Dr. F. I. SPRIGGS. They are selections from the papers issued from Duff House from its opening in September, 1913, to the present time. Some of the articles are reprints of contributions to medical journals, as, for instance, the article on "Meat Diet in Sprue" which appeared in the *BRITISH MEDICAL JOURNAL*, August 7th, 1920. The new matter in the book includes a manual for the use of diabetic patients, in which the nature of the disease is explained; every little detail of the measurement of food and examination of the urine is described, and the principles of treatment made clear,

<sup>4</sup> *L'Orthopédie en Clinique*. By J. Privat. Paris: A. Maloine et Fils, 1923. (Cr. 8vo, pp. 817; 595 figures. Fr. 25.)  
<sup>5</sup> *Duff House Papers*. Edited by F. I. Spriggs, M.D., F.R.C.P., Vol. I. Oxford Medical Publications. London: Henry F. owder, and Hodder et al. Stoughton. 1923. (Double cr. 8vo, 19. x + 217; 129 figures, 1 plate. 30s. net.)

<sup>3</sup> *Oreillons, Coqueluche, Grippe, Erysipèle Médical*. By Dr. H. Barbier. Paris: Octave Doin. 1922. (4 1/2 x 7 1/2, p. 308. Fr. 10 net.)

so as to secure the patient's co-operation. This is supplemented by an article on diabetic cookery by the diet sister of Duff House, and an account by the gardener of the best means of securing a good supply of greens, salads, and other vegetables suitable for diabetics.

Other new matter in the present volume includes a detailed account of the x-ray technique employed at Duff House for examination of the alimentary canal. Seventy pages, profusely illustrated, describe the examination of each section of the intestinal passage, and interpret the appearances revealed by x rays in pathological conditions commonly encountered.

The wide field covered by the different papers should make the volume of interest to many members of the medical profession, and the service it is capable of rendering is certainly enhanced by the attractive way in which the book is printed and the excellent illustrations with which it is embellished.

### PROTISTS AND DISEASE.

THE difficulty of deciding whether certain unicellular forms of life belong to the animal or vegetable kingdom led Haeckel to suggest that the name Protista should be given to these primitive creatures, and Mr. J. JACKSON CLARKE has adopted this classification in his book *Protists and Disease*.<sup>8</sup> He has previously published five books, four of which have appeared under the title of "Protozoa and Disease"; in these he has described the organisms he has observed in molluscum contagiosum, small-pox, syphilis, and cancer, and believes to be the cause of these diseases. The present book is a restatement of his case. The title has been altered because he has come to the conclusion that the organisms he describes are not protozoa but protists allied to Synchronaceae; he has set out to establish the biological relationship of these organisms with well recognized species. The subject is introduced by a review of unicellular forms of life and a consideration of many different botanical forms which do not always appear under their more familiar names, and whose connexion with the main thesis of the book is not at first apparent. It is with greater interest that the reader arrives at an account of *Plassomyxa contagiosa*, described as the pathogenic member of the Plassomysineae responsible for the disease molluscum contagiosum. Here the author describes vividly what he has seen and the way in which the parasite may be cultivated. He has found a similar parasite in sarcoma, the cause of which he considers to be a parasite that first invades the nuclei of connective tissue cells, escapes thence into the cytoplasm of the host cell, and thence again into the intercellular spaces. The parasite subdivides, "either with or without the formation of chromatium," into amoebulae which tend to assume a stellate form. Corresponding ideas are advanced with regard to small-pox, syphilis, and hydrophobia.

It is apparent that the author's views as to the causation of these diseases are not in accordance with those held by the majority of pathologists, and it is for this reason that we would commend the book to them rather than to other members of the medical profession. When Emerson said, "Truly speaking I can receive instruction from no man, but provocation," he indicated the benefit that can be derived from contact with ideas the opposite of our own. Still we must warn even this group of readers that the book has certain defects of construction, one of which is that the author has a way of not always sticking to the point.

### NOTES ON BOOKS.

PUBLIC health nursing is a term "devised to describe more fittingly an infinite variety of functions" which are "the extension of an old service variously known as neighbourliness, sick visiting, and visiting nursing." So we are told in the introduction to a readable and useful work<sup>9</sup> containing an historical survey of the development and present position of professional nursing service, not merely in America, whence the book comes, but also in the old world. Public health nursing in the sense indicated does not imply the existence of sickness. It includes domestic education in the prevention of sickness, and so corresponds in the sphere of the nurses to preventive medicine in the sphere of the doctors. Obviously it embraces the work of health visitors in this country and

visiteuses d'enfants in France. The author goes far back into history, discussing nursing in the Roman Empire and in the Middle Ages, tracing the beginnings of sanitary service; giving some account of the work of Florence Nightingale and the founding of district nursing under Rathbone in Liverpool, and the later specializations of nursing in war and peace. Emphasis is laid on the teachings of experience that nursing should not be combined with the distribution of doles, and that for material relief the needy should be referred to agencies established for the purpose. That principle was established in the early days in Liverpool, and was also learnt in America, as in Buffalo, where "no relief is now handled by the [Nursing] Association, but every nurse is taught to refer to the proper agency cases within her section requiring material aid." The services of the nurse are not confined to the needy, nor are they limited to the sick; "her work is pre-eminently constructive, and if her training as a nurse is essential her ability as a teacher is equally so." Miss BRAINARD's book can be heartily recommended as well arranged and well written, and distinguished alike by knowledge and wisdom.

There has of recent years in this and other countries been a large development of organized physical exercises. Games will always have first place in the affections of youth, but there are occasions and places where games are insufficient for all those who need the physical stimulation and exercise which organized instruction can and should give. Where there are large bodies of children or young people some organization of physical exercises in which all should take a share is necessary, otherwise some (and often those who need this training the most) by reason of shyness, diffidence, or a feeling that theirs is not to strive and win at games, may be left without the very discipline they need. Major F. W. STEVENS, late of the Essex Regiment, has written a very useful and compact little handbook of such physical exercises.<sup>6</sup> He has striven to make as complete a series of exercises as can be carried out in a moderate-sized gymnasium, with a minimum of equipment, and of such general interest to the performers as will attract them to engage in this training of their own free will. The exercises are composed in such fashion that they can be performed to musical accompaniment, which adds much to the interest and enjoyment of the pupil, and naturally induces grace of movement. Besides the set forms of organized movements suggestions are included for a number of brisk games which may be played in the gymnasium during intervals, and in these full play can be given to the exuberant vitality of youth and the natural desire for freedom of movement. The book is well illustrated and conveniently arranged, so that it should form a handy guide to instructors and teachers generally.

The second edition of the second volume of Professor W. BIRK's book on diseases of children,<sup>7</sup> dealing with conditions past the age of infancy, is, with the exception of a few minor alterations, substantially the same as the first, published some eighteen months ago. It has apparently proved itself a popular textbook for students and practitioners in Germany. Covering a wide field, it gives a very condensed account of symptomatology and treatment. Out of a total of about 340 pages some 120 are allotted to the acute infectious fevers, tuberculosis, and syphilis. The remaining subjects are crowded into a space that scarcely allows of adequate presentation. Those who prefer such a severe abridgement may find it a serviceable book.

The first volume of the *Minutes of the Dental Board of the United Kingdom and of its Various Committees*<sup>10</sup> has been issued. It covers the period from December 7th, 1921, when the first meeting of the Board was held, to December 31st, 1922. The Board consists of a chairman, the Right Hon. Francis Dyke Acland, M.P.; three persons, not registered medical practitioners or dentists, appointed by the Minister of Health, the Scottish Board of Health, and the Lord Lieutenant of Ireland, respectively; three persons appointed by the General Medical Council—namely, Mr. H. J. Waring, F.R.C.S., Sir James Hodsdon, K.B.E., F.R.C.S. Edin., a member of the Branch Council for Scotland, and Sir Arthur Chance, F.R.C.S.I., a member of the Branch Council for Ireland; and six persons engaged in the practice of dentistry—two appointed by the Privy Council, two by the Minister of Health, one by the Scottish Board of Health, and one by the

<sup>8</sup> *Protists and Disease*. By J. Jackson Clarke, M.B. Lond., F.R.C.S. London: Baillière, Tindall, and Cox. 1922. (Fcap. 4to, pp. xii+223; 1 plate, 61 figures. 15s. net.)

<sup>10</sup> Board by Constable and Co., Ltd.

Lord-Lieutenant of Ireland. The volume also contains six appendices, including the standing orders of the Board, reports of the Examination Committee, and the warning notice as approved by the General Medical Council on November 30th, 1922.

## THE PREPARATION OF PATIENTS FOR OPERATION.

We have received from Dr. T. M. Allison of Newcastle-on-Tyne a letter in which he condemns the administration to patients before operation of purgatives and enemata, a method which he implies is followed in some hospitals and nursing homes as a matter of routine. He writes:

The surgery of the present day, which I greatly admire, has two great and glorious achievements to its credit—anaesthesia and asepsis. But it has still certain reproaches, one of which is the "preparation" of patients for operation.

How many of the patients who die on the operating table die, not from the operation, nor from the anaesthetic, but from the "preparation"? A nervous patient, afraid of the unknown (and most of us are afraid), is given a barbaric dose of unnecessary aperient the night before the operation, is kept awake the most of the night, and rendered unfit for the morrow by sleeplessness, griping pain, and getting out of bed. Instead, therefore, of refreshing sleep, the patient is worried physically and mentally most of the night, and the last chance of repose is banished by an enema in the early morning. Anything less scientific can hardly be imagined, as the patient goes on to the table "prepared" rather for collapse than for operation. If this surgical fetish is in any way desirable, might I suggest that it be done two or three days before the operation? Before the operation, in my opinion, it would be wiser and kinder to give 2½ grains (each) of veronal and phenacetin, with half a grain of caffeine at 7 o'clock the previous evening, and/or a grain of opium at 9 p.m.; personally I would rather have both than the castor oil and the enema.

Happy, indeed, is the emergency case, even with a ruptured gastric or duodenal ulcer (in whom no "preparation" is possible) in comparison with the "prepared patient," and it would be both interesting and instructive if some of our hospital surgeons would give their impressions and statistics on these two classes of cases.

The matter is one of considerable importance, and it has seemed worth while to gather together the opinions some surgeons have expressed upon it.

The suggestion that purging before an operation is harmful rather than beneficial to the patient is not, indeed, new. So long ago as 1861 Oliver Wendell Holmes said: "If it were known that a prize-fighter were to have a drastic purgative administered two or three days before a contest . . . no one will question that it would affect the betting on his side unfavourably." The custom of purging has, however, a long history to support it, dating back beyond humoral pathology to the dawn of civilization. Purgatives were given to healthy persons about to undergo any ordeal—those starting on a journey were purged; those about to be bled; those about to be tortured for the extortion of confessions.<sup>1</sup> As early as 1776 Cullen<sup>2</sup> questioned the value of "these pretended preparatory courses of medicine. . . . Other mischievous effects have sometimes appeared."

It would appear that some teachers of surgery continue to recommend the employment of the purge and the enema before operation, and that the practice is a routine in many hospitals and nursing homes. J. P. Warbasse,<sup>3</sup> for example, in 1918, says: "The day before operation a laxative should be given. . . . On the morning of the operation it is well to give an enema." A. Carless,<sup>4</sup> in 1920, says: "During the previous day an effective purgative is given, and an enema may be desirable in the morning." G. E. Gask,<sup>5</sup> in 1920, says: "The bowel should be well cleared out by a dose of castor oil followed by an enema early in the morning of the day of operation." On the other hand, a review of recent literature shows that there is a decided tendency among many surgeons to discontinue pre-operative purgation or to diminish its severity.

E. Walker<sup>6</sup> reported that he had not used purgation as a preparation for operation for more than two years, and that he was convinced that his patients suffered less with tympany and recovered more quickly. J. E. Moore<sup>7</sup> reported favourable results from the disuse of pre-operative catharsis. Yelverton Pearson<sup>8</sup> said that he did not give purges later than the morning of the day previous to operation, and that no enema was permitted as a preliminary to operation. Kocher's opinion<sup>9</sup> was that no patient should come to operation with a full bladder or rectum. On the morning of the operation a warm soap-and-water enema should be administered. The intestinal canal must be emptied, but

the action of the purge should have ceased by the day of the operation; two days before the operation the patient was given one to two tablespoonfuls of castor oil or a dessertspoonful of natural Karlsbad salts. G. W. Crile<sup>11</sup> warns against starving a patient too long and purging too severely before operation, because it interfered with the normal tone of the intestine. W. J. Mayo<sup>12</sup> has pointed out that the difficulties and dangers of using clamps in gastro-intestinal operations are increased by purgation. W. C. Alvarez<sup>13</sup> who gives a good summary of the literature on the subject, is of the opinion that the purgation of patients before operation is not justifiable. He says that experienced nurses have told him that they preferred looking after an emergency to a prepared abdominal case, and that most surgeons whom he consulted on the subject stated that they gave up the routine purge at the suggestion of their nurses. They all agreed that the stormiest after-courses and the worst "gas pains" were met with in the elaborately prepared cases. His experimental work on the intestine confirmed him in his opinion.<sup>14</sup> Purgation caused hyperaemia of the entire intestinal mucosa; the majority of purged animals showed increased intestinal gas and often congestion of the mesenteric circulation; purgation made the bowel react very poorly to drugs, the doses sometimes requiring to be increased one hundred times to produce any effect. L. A. Enge<sup>15</sup> reviews the work of others on this subject, and concludes from his own clinical observations on a series of cases that the strongly purged bowel is more difficult to handle than the unpurged bowel on account of coagulation and distension, and that patients who have not been purged are comparatively free from "gas pains." He believes that an enema will clear the lower bowel sufficiently for any operation. It is interesting to compare two successive editions of *Pye's Surgical Handicraft*, edited by W. H. Clayton-Greene. In the seventh edition (1916) the following words are found: "It is better in most cases to purge the patient two days before the operation and to administer the enema the evening before." In the eighth edition (1919), however, we find the following: "It is not necessary to starve or purge our patients in the drastic manner customary some years ago. An aperient such as a patient has been used to, or a small dose of castor oil, should be given forty-eight hours before. Except in rectal cases the enema may be omitted." E. Wyllies Andrews<sup>16</sup> is strongly of opinion that a simple enema the night before is ample preparation for most surgical procedures.

Sir Berkeley Moynihan<sup>17</sup> says: "Flatulence is a troublesome complication, not only of abdominal, but of other operations also. Its cause is uncertain. My own view is that it chiefly results from the starvation and purgation which are almost universally considered a necessary part of the ritual of deliberate operations. Both are certainly undesirable and are possibly harmful. . . . An enema generally clears the colon quite as much as is necessary." Sir William de Courcy Wheeler said recently,<sup>18</sup> regarding his own practice, that no laxatives to cause purging were ever given to patients before operation, and no enema was given on the morning of operation.

The literature of surgery is not so full as it might be upon this particular point. The pre-operative treatment of patients—and particularly the giving or withholding of purgatives—is frequently skimmed over in textbooks on surgery and operative surgery, and when it is mentioned at all the subject is usually buried in articles pertaining to other subjects. J. F. Binnie,<sup>19</sup> for example, states that, following Wetherill, he has discarded post-operation catharsis; but he does not say (so far as could be ascertained) whether or not he advises purgatives before operation. For a long time it has been recognized as an axiom in surgery, following the teaching of Moynihan, that an aperient should never be administered to a patient with a suspicious acute abdominal lesion. The consensus of surgical opinion to-day is apparently towards extending this by discontinuing the giving of purgatives before operative procedures of whatever nature.

## British Medical Journal.

SATURDAY, MARCH 17TH, 1923.

### THE RIGHTS OF A REGISTERED MEDICAL PRACTITIONER.

WE desire to draw the attention of the medical profession of this country to an insidious attack now being made by a Government department upon its legal rights. The whole subject is receiving the close attention of the British Medical Association and of the medical members of Parliament acting in concert, and (as will be seen from the Current Note published in this week's SUPPLEMENT) steps are being taken to defend the threatened liberties. Our purpose here is to dwell upon certain matters of principle in order that the profession may understand the larger issues that are at stake.

Section 31 of the Medical Act, 1858, on "privileges of registered persons," laid down that every person registered under the Act should be entitled, according to his qualification or qualifications, to practise medicine or surgery, or medicine and surgery, as the case might be, in any part of Her Majesty's dominions. The Medical Act, 1886, declared, by Section 6, that a registered medical practitioner was entitled to practise medicine, surgery, and midwifery in the United Kingdom, and (subject to any local law) in any part of Her Majesty's dominions. The effect of these Acts was to set up one class of legally qualified practitioner of medicine and to give him one name—"registered medical practitioner." From that time to this every registered medical practitioner has had in the eyes of the law an equal standing with every other registered medical practitioner.

Registration, while it imposes certain legal obligations, confers also certain privileges which are common to every person registered under the Medical Acts. A legally qualified medical practitioner may choose to practise his profession, or may not so choose; he may be one day in practice and another day not in practice; that is his own concern. So long as his name appears on the *Medical Register* he is a registered medical practitioner, with all the rights and responsibilities that that term connotes. The law does not ask whether a doctor is in practice; it asks if he is registered. Acts of Parliament have not hitherto distinguished between practitioners in active practice and retired practitioners; nor have they attempted to define the term "medical practice." In this the Legislature has shown wisdom and common sense. One doctor may practise all the year round, and another (who has taken, say, to rose growing) may practise once in six months by prescribing a dose of calomel or opium for his head gardener. The point is that every registered practitioner is potentially in practice. A grocer cannot carry on his trade without a shop, but a doctor can exercise his profession without a brass plate; he takes his professional knowledge with him into retirement, and no one can say when he may find occasion to employ it. In national or local emergencies there is no such person as a "retired" doctor.

But the Home Office, it appears, has other views. Not content with making different rules for insurance practitioners and for practitioners-not-on-the-panel in regard to the signing of prescriptions for a particular group of "dangerous drugs," the Home Office now proposes to discriminate, by words included in an Act of Parliament, between registered medical practitioners in actual practice and registered medical practitioners not in actual practice. For proof that this is so we refer our readers to Section 3

of the Dangerous Drugs and Poisons (Amendment) Bill, introduced recently into the House of Commons by the Home Secretary. (See SUPPLEMENT, February 24th, 1923.) With the motive for this innovation we are not at the moment concerned; nor with its obvious futility. What we wish to point out is that the Home Office is endeavouring for its own purposes to bisect the body of registered medical practitioners of this country.

This, however, is not the only infringement of the rights and liberties of the registered medical practitioner. Last summer the Home Office informed the British Medical Association that it was proposing to amend the regulations under the Dangerous Drugs Act, 1920, so as to forbid the dispensing of a prescription for "the drugs" written by a medical practitioner for his own use. The Medico-Political Committee recognized at once that this proposal was both futile and vexatious, and so reported to the Council of the Association. The Council informed the Home Office that the proposed new regulation was an undesirable limitation of the privileges of a registered medical practitioner without any compensating advantage to the public. But the Home Office, unmoved by argument, proceeded upon its course, and tacked on to Regulation 5 the words, "The prescription shall not be given for the use of the prescriber himself." In the debate on the amending bill in the House of Commons on February 28th the inconvenience and the absurdity of this prohibition was pointed out in cogent terms by two medical members—Dr. L. G. S. Molloy and Sir Sydney Russell-Wells. To our mind it is of importance because it raises a matter of principle. We perceive in this, as in the use of the words "in actual practice," the thin end of a wedge.

### THE SCHOOL OF HYGIENE.

It was recently stated in a London newspaper that, owing to a further act of generosity on the part of the Rockefeller trustees, the appointment of a director of the projected School of Hygiene would be able to be made before the school has a bodily existence. This means, we presume, that the director will have ample opportunities of conferring with his future colleagues, the professors designate—the designation of the professors should speedily follow the appointment of a director—on the spiritual future of the institution.

It is perfectly consonant with the psychology of the English race that the actual level of knowledge of preventive medicine and hygiene should be higher than its academic status, that the practical value of the instruction given should be greater than the apparatus of teaching would imply. In only a minority of English universities can the doctorate be attained by proficiency in the subject; in some, ignorance of the principles of preventive medicine does not form a barrier to graduation. Just as in the sister profession of Law the merely formal requirements of the Inns of Court, sixty years ago, led to no great scandal because those who intended to practise took pains to learn their work in the chambers of adepts, so the aspiring specialist in public health has had to take pains to learn his business without academic stimulation.

But one evil of the old system in the Inns of Court was, as that shrewd observer Walter Bagehot noticed, the discouragement of the philosophical jurist and the encouragement of the acute but mentally limited caselawyer. Something of the same kind has happened in our profession. In the training of the younger men all the emphasis has been on technical acquirement. It would not be going too far to say that most young candidates for posts in the public health

\* The connotations of the words are not identical: both might be covered by conservative medicine, an expression Farr wished to introduce fifty years ago.

service are far better acquainted with the inside of a bacteriological laboratory and with the provisions of the Public Health Acts than with the principles of epidemiology. We doubt whether ten per cent. of the successful candidates in any D.P.H. examination could accurately describe the steps leading up to any of the classical inductions of Simon, Ballard, Farr, or Thorne Thorne, though they are no doubt acquainted with the results, which are summarized in every textbook.

A broadening of outlook is the function of a university education. Without it a diffusion of interests easily degenerates into slovenly omniscience. We had far rather see our public health services officered by the narrowest of technicians than by bookish philosophers, but there is no need to run from one extreme to the other. It will be the duty of the new School of Hygiene to raise the general level of culture: directly, by offering a well balanced course of instruction to its post-graduate students; indirectly, by setting before the profession a higher intellectual ideal than the existing system of public health training can in itself afford.

These ends can only be compassed by close and loyal co-operation between the members of the staff of the new institution. We mean by this much more than the ordinary good feeling which informs the relations within any group of gentlemen. It is so easy for any man to beguile himself into thinking that he must be right in demanding more and more time for his branch of knowledge, and that to acquiesce in a time table which allots fewer hours to his subject than to someone else's subject is disloyal to the interests committed to his charge. Because of this tendency, we think the appointment of a director and staff well in advance of the opening of the school is a statesmanlike act. A new professor in an old university, however enthusiastic, has few temptations to attack at once the existing order. In a new institution the case is different. It is unthinkable that any men of science would accept a programme imposed upon them by an external authority, equally incredible that they should arrive at a concordat without much discussion. This discussion, aided, we should hope, by a ventilation of the subject throughout the whole profession, ought to begin in the very near future.

#### THE OCTOCENTENARY OF ST. BARTHOLOMEW'S.

Eight hundred years ago this spring two buildings were being erected on a playground just outside the walls of the City of London, which was then called *Norman's Land*, though it has long been known as *Smithfield*. Both buildings, in accordance with the faith of the times, were intended to be religious foundations—the one for the good of the soul, the other of the body; the one a Convent of Augustinian Canons, the other a Hospital where the sick poor could be tended until they recovered, and women with child until they had been delivered. The zeal and piety of Rahere raised them simultaneously. In early life a member of the Court of Henry Beauclerc, but saddened perhaps by some loss in the wreck of the *White Ship*, he had turned his thoughts to religion. Becoming himself the first Prior of the new Convent, he arranged that the two foundations should be independent yet associated, and so long as he lived they worked in harmony. The canons recommended patients to the hospital and gave a tithe of their bread with the leavings of their meat, fish, and drink to feed them; the hospital, when supplies abounded, gave to the canons anything of which they lacked. The Prior of the Convent and the Master of the Hospital were independent of each other, though both were chosen by the convent. When a new sister was admitted at the hospital she was chosen by the prior upon the recommendation of the master and brethren of the hospital. She swore fidelity to the prior and the convent, but obedience to the master of the hospital. Twice in a year, on Palm Sunday and Ascension Day, the master and brethren of the hospital went in solemn procession

to the convent church and there made their offerings and oblations. Finally, they and their patients had the right of being buried in the priory cemetery. Such an interrelation did not last long. Canons who preached charity sermons for the hospital sometimes applied the proceeds to the uses of the convent; whilst the hospital chaplains when they begged in the name of the priory occasionally distributed the contents of their bowls amongst the patients in the hospital. Hence arose dissensions, made more acute by permission from Pope Calixtus for the hospital to have a cemetery of its own. Such permission nowadays would hardly seem a reasonable *casus belli*, but at that time many wealthy citizens, in token of humility, chose to be buried amongst the poor, and a private burial ground was a source of considerable income. The squabbles continued for many years, and repeated appeals were made to Rome, until, in 1373, the convent and the hospital were virtually separated from each other by the arbitration of Simon of Sudbury, Bishop of London. The separation preserved the hospital. More than a hundred and fifty years later, when the priory was suppressed and its revenues were confiscated, the endowments of the hospital, after passing into the hands of King Henry VIII, were partly returned at the urgent solicitation of the Mayor and Corporation of the City of London. The independence of the two foundations remained even after the Reformation. The convent and its precincts became the parish of St. Bartholomew-the-Great, with a portion of the old priory church as the parish church; the hospital became the parish of St. Bartholomew-the-Less, with its principal chapel, dedicated to the Exaltation of the Holy Cross, as the parish church. All trace of the conventual buildings gradually became lost, and the church was allowed to fall into decay, whilst the hospital continued its beneficent work as a secular institution. It is somewhat remarkable, so persistent is custom in this country, that the hospital still celebrates the anniversary of its foundation, though in a debased form, by the annual "View Day," while the church has no such memorial. After the Reformation the governors of the hospital were summoned to meet at seven o'clock on a March morning for the purpose of attending divine service in the church, and afterwards to view the hospital. In these more degenerate days the viewing of the hospital is done at half-past two in the afternoon of the first Wednesday in May. The earlier hour in the earlier month was doubtless a survival of the pre-Reformation service, like that which is still held on May Day morning at Magdalen College, Oxford. At any rate, it is quite in accordance with what little is known of Rahere's humour that he should choose for the dedication a day when the Mass begins with the Introit, "*Laetare, Jerusalem, et facite Conventum.*" The Rector and Churchwardens commenced the Octocentenary celebrations at St. Bartholomew's-the-Great on mid-Lent Sunday (March 11th) with an appropriate service, which was largely attended, both in the morning and in the evening. Similar services will be held next Sunday. For many years the separation between the two bodies was complete, but for a short time when Sir William Savory was Surgeon to the Hospital his only son, Boradale, was Rector of St. Bartholomew's-the-Great. From this time onwards there has always been a friendly interchange, and when the church lacked anything in the matter of funds the hospital by its medical and surgical staff have assisted in supplying the want. The hospital proposes to celebrate its own octocentenary at the beginning of June, and without any cost to itself, for the City in its corporate capacity and the Governors have always been proud of their great charity.

#### THE CONTROL OF BLOOD SUGAR.

A SERIES of communications of considerable interest regarding the mode of action of insulin are appearing by L. B. Winter and W. Smith, who are working in the Biochemical Laboratories at Cambridge. In a paper published in our columns on January 6th (p. 12) they related the results of experiments which showed that the sugar present in normal blood was

not the stable  $\alpha$ ,  $\beta$  form of glucose but was an unstable form of glucose, and probably  $\gamma$  glucose. They found, however, that the sugar in the blood of diabetics was probably the  $\alpha$ ,  $\beta$  form of glucose. They suggested that the tissues could only utilize  $\gamma$  glucose, and that an enzyme exists normally which changes the  $\alpha$ ,  $\beta$  form of glucose to  $\gamma$  glucose, and that diabetes was due to the absence of this enzyme. In a second communication<sup>1</sup> they showed that extracts of pancreas and liver could change the rotatory powers of glucose *in vitro*, and that this change was accelerated by the addition of phosphates. Work by Embden and Laquer has shown that a sugar-phosphoric complex is probably an intermediate stage in the utilization of glycogen by muscle. These conclusions suggest, of course, that the action of the pancreatic hormone, insulin, is to enable the change from  $\alpha$ ,  $\beta$  glucose to  $\gamma$  glucose to occur, and that one stage in this change is the formation of a sugar-phosphoric complex. In their last communication<sup>2</sup> Winter and Smith have published a very surprising conclusion, which may prove to be still more important. An essential stage in the metabolism of sugar by yeast is believed to be the formation of a sugar-phosphoric complex, and this suggested the idea that an extract of yeast might take the place of pancreatic extract. They obtained a solid extract of yeast which on injection lowered the blood sugar of rabbits and caused convulsions in rats. The suggestion is, of course, that yeast extract may be found to have an action similar to that of insulin. Though this may prove to be of profound importance, it must be clearly understood that at the present stage it must be regarded as an interesting suggestion rather than an established conclusion. Yeast extracts contain a number of substances with powerful pharmacological actions, and numerous substances—for example, peptones—can lower blood sugar, and many substances also can cause convulsions in rats. Until we have information as to the action of the yeast extract in diabetes it is impossible to form any conclusions as to the significance of the results here mentioned.

#### RHYTHM IN LIVING ORGANISMS.

SIR ARTHUR SHIPLEY, F.R.S., Master of Christ's College Cambridge, lectured to the Royal Institution on March 6th on rhythm in living organisms, especially that kind of rhythm which appeared to be inherent in the organisms and not dependent altogether on diurnal or seasonal change. He instanced the organisms which make the sea appear to be phosphorescent at night. It is not the case, as might be supposed, that these organisms merely need the darkness in order to exhibit their phosphorescence. If they are taken to a photographer's dark room they will still show phosphorescence, not in the day-time, but only after nightfall. The small worms of the genus *Convoluta* bury themselves in the sand when the tide rises and reappear on the surface with the ebb, but they still show this same action at the time of the tides when taken far from the seashore and placed in an aquarium. Another example is the seasonal growth of trees, evidenced by the annual rings; but if a deciduous tree be transplanted to the tropics, with virtual uniformity of temperature all the year round, the rhythm of seasonal growth will persist, at all events for a time. There is a rhythm in the bloom of flowers in the densest tropical forest, and a rhythm in the reproductive cycles of deep-sea organisms, although in the depth of the sea the influences of climate, temperature, season, light, and sound are withdrawn, and, with complete uniformity of external conditions, the secret of the rhythm must be within the organisms themselves. Rhythm in some living organisms appears to depend on the moon. A sea urchin in the Red Sea shows a definitely rhythmic growth and declension with the moon's phases, though similar sea urchins in the Mediterranean show no such rhythm. Some flowering plants are said to direct their stems towards the moon and follow its course at night. Sir Arthur Shipley pointed to the other instances of rhythm

seen in spiral movements of the growing tendrils of plants, the action of muscles and organs, including the excretory organs, and the life of communities, alike of insects and of the civilizations of mankind.

#### CHANGES IN LIVING CELLS DURING GROWTH AND DIVISION.

DR. T. S. P. STRANGEWAYS, who has given prolonged study to the remarkable changes which take place in living cells during growth and division *in vitro*, has recently published in the *Proceedings of the Royal Society*<sup>1</sup> an account of what he has observed in cultures from the choroidal cells of chick embryos and the cartilage cells from knee-joints of adult fowls. By cultivating fragments of tissue in a drop of chick plasma, to which embryo chick extract has been added, and keeping the microscope and cultures at a temperature of 39° C., he was able to make a series of continuous observations, and the seventy-eight drawings he has produced illustrate the changes seen in a living cell from one division to another. The outline of a growing cell is constantly changing; larger or smaller processes of cytoplasm are thrown out and withdrawn as in amoeboid movement; the cells tend to assume an elongated shape, and by these activities may slowly change their position. Rod-like structures, described as mitochondria, may be seen in the cytoplasm moving from one place to another, and minute refractile granules move past and round the nucleus, but never enter this structure. The clearly defined nucleus may be round or oval and it wanders about the cell freely, being sometimes at the centre, at other times at one or other pole, its position depending largely on the movements of the cytoplasm. When large cytoplasmic processes are thrown out the nucleus may pass out with these processes and be drawn back if they retire. When first formed the nucleus is relatively small, but it soon increases in size and usually contains one or more irregularly shaped structures which stain intensely with iron haematoxylin; they are referred to provisionally as nucleoli. Brown pigment rods may also be seen moving about rapidly and irresponsibly in the cytoplasm. When about to divide the processes of cytoplasm retract and the cell assumes an oval or rounded shape; the nucleoli become fainter and appear as hazy granules. A number of fine threads may be seen in active writhing movement within the nucleus; the outline of the nucleus disappears and the chromosomes rapidly arrange themselves at right angles to the spindle, which with the centrosomes is visible at this stage. A few minutes later the chromosomes begin to draw apart from the centrosomes and show clearly as finger-like processes, being drawn towards either pole of the cell, which has by this time taken an oval shape. At this stage Dr. Strangeways describes a most interesting development in the outline of the cell. "Small balloons of cytoplasm project from the surface of the cell, remain for a few seconds and then collapse. The granules in the cytoplasm can be seen flowing in when the balloons are formed and streaming out when they collapse. This movement continues for about six minutes, new balloons being formed as the others collapse. This balloon formation is unlike amoeboid movement, and appears due to local changes of surface tension." The cells divide during this stage, and the two masses of cytoplasm pull apart, being joined only by fine filaments of cytoplasm and a few mitotic threads. The granules in the cytoplasm do not appear to take any active part in mitosis, but are in a state of active movement, flowing from one side or other of the two cytoplasmic masses, and they are ultimately distributed in fairly even numbers between the two newly formed cells. The time from the beginning of one division to the beginning of the next is between eleven and twelve hours, and the actual period occupied for complete division of a cell is on the average about thirty-four minutes. The constant activity of the living cell is clearly shown by these observations, for the cell and the structures within it are never at rest during growth and division.

## TREATMENT OF MENTAL DISORDERS.

BRIEF reference has already been made to Professor G. M. Robertson's annual report on the work at the Royal Hospital at Morningside; but as is his custom, he does not confine himself to a mere record of administrative and statistical details, and we may now mention some of the comments and observations he makes, which are of general public interest in connexion with the work of his hospital, which is a centre of active psychiatric work and is extending its sphere of usefulness in various directions. It is proposed to increase the accommodation and standard of treatment for private patients paying the lower rates of board. Not only will the patients and their relatives benefit by these proposals, but so will the community at large, as any measure which tends to prevent a patient from becoming a burden on the rates is of direct advantage to the public. Four homes for nervous cases have been established by the managers where the family physician can treat his patients under the supervision of an experienced staff till they recover, without the necessity of certification or asylum treatment. Scotland is fortunately situated, as Professor Robertson observes, in having a law which enables this form of early treatment to be conducted in such homes. In view of the great advances made in psychotherapy and the importance of this form of treatment, a psychological assistant physician has been appointed whose duties are almost entirely restricted to psychological investigation and treatment. Professor Robertson believes that psychotherapy, including psycho-analysis, is now settling down at last into its right place in medicine, and that, even if comparatively few psychoses are amenable to treatment by these means, they give us an understanding of the patient's symptoms and mentality useful in general treatment and management. Moreover, such insight is of the greatest value in preventing the development of definite mental disorder, provided persons come for advice and treatment at an early stage of their mental troubles. Amongst matters of general interest considered is that of the Church and healing—a subject which has been somewhat prominent lately. Professor Robertson's vigorous comments are written from an eminently common-sense standpoint. "At no time," he writes, "are the ministrations of the clergy of more influence and value than during prolonged sickness and even during periods of crisis. This is gratefully acknowledged by every physician. There exists a temptation, however, at such times, which a few clergymen appear unable to resist, of absorbing the professional sphere and the functions of the physician. These persons, though uneducated in medical science, which involves the most laborious training connected with any of the learned professions, pose as healers. . . . These practitioners, whose art is indistinguishable from a lukewarm Christian Science . . . cure by the possession of a mysterious 'gift of healing,' or by something not essentially different from the performance of a miracle, the initiation of which is their peculiar prerogative. No one limits the possibilities of spiritual or divine power, and the cure of all diseases, by whatever means, is through divine agency. But the laws of space and gravitation are no more an obstacle to this power than are those of anatomy and physiology, for mountains may be removed, yet we do not hear of the clergy initiating miracles in this sphere or performing feats of an engineering kind. When the foundations of the pillars supporting the dome of a great church subside . . . they open subscription lists and call in the services of an architect, yet they rush in to restore a temple not made with hands. We hope that Scotland, with its strong and pervading religious sense and with its famous medical schools, will be the last country in the world to regress to that primitive phase of civilization in which the functions of the priest and of the medicine man were in the person of one individual, whose pharmacopoeia consisted mainly of incantations and of magic for the treatment of every ill." The report contains some interesting observations on the notable diminution of deaths from general paralysis in England and Wales during the years 1919, 1920, and 1921. Professor Robertson suggests that the lessened consumption of alcohol

and the early methods of treatment may be factors concerned in the remarkable decrease which has occurred. It may be observed that apart from the diminished number of deaths from general paralysis many psychiatrists have noted alterations in the clinical symptoms and course of the disorder. Many cases are atypical; remissions are increasingly common; and the total duration of the illness is often much longer than was formerly the case. A large number of these cases first showed signs of neuro-syphilis while in the army, and thus received treatment in the very early stage of the disorder. This may perhaps account for the protracted course of the disease. In discussing the treatment of service patients, Professor Robertson suggests that, in spite of the advantages of allowing the surplus of the pension to accumulate, a greater part of the pension should be utilized for treatment on a more liberal scale than at present, while the patient is in the mental hospital.

## THE FATE OF THE CIVILIAN IN FUTURE WARS.

AN imaginative and idealistic sketch of future warfare was presented to the War Section of the Royal Society of Medicine, at its meeting on March 12th, by Colonel J. F. C. Fuller, D.S.O., General Staff Officer, Staff College, Camberley, in introducing a discussion on some of the medical problems of future warfare. Colonel Fuller (who is not a medical officer) declared that war, always more a psychological than a physical problem, had been wrongly regarded in the past as a competition in slaughter. With the development of psychological science it would be more truly envisaged as a struggle of mind against mind, or of genius against mental mediocrity, in which bloodshed and destruction would be reduced to a minimum. The element of destruction in warfare was not only non-essential, but even disadvantageous to the victors; the obsession to kill would be gradually eradicated from the military mind. During the last war it was not muscle but brains that decided the victory. The decisive weapons of the future would be ethical, economic, and only in a restricted sense military. Ethical warfare would rely upon highly organized propaganda directed to demolish the national will of the enemy and discredit his cause. Economic warfare would attack the national will by way of the national stomach. Military warfare would take the form chiefly of gas attacks from the air upon city populations; they would have the effect of temporarily paralysing but not destroying the community. The man who first thought of mustard gas dominated to rank with the discoverer of gunpowder. Chlorine gas was in a different category, but mustard gas would make it possible to wage war without causing widespread death or mutilation. Aircraft would be used on a large scale, not for explosive bombing, but to envelop the people below with some vesicant chemical which would render them incapable of resistance. Indeed, it might be that future war would take the form of anaesthetizing the enemy. He pictured 500 enemy aeroplanes over London putting London to sleep for forty-eight hours, and then landing enemy police, who, with the support of tanks, would control the situation until the surrender and indemnity were forthcoming. Such a manoeuvre would be far more profitable to the enemy than wholesale destruction, and the defeated would not, save in dignity and possessions, be permanently damaged. Future warfare would be astonishingly rapid. The target would be the civil population. Upon that population war would break with the terror of a mental earthquake. Success would depend upon the delivery of the psychological "knock-out blow." Such warfare would mean an enormous increase in mental illness. What was known in the past war as shell shock would be widely prevalent among civilians. Part of the work of the medical profession in peace should be to prepare the public nerve for the shock of psychological attack. Each individual must have a first-aid outfit, not in his knapsack, but in his mind. If the public mind could be prepared for the character of future hostilities the attack when it came might fail because it would not produce the anticipated terror. It was only the unknown and unexpected

which caused the paralysis of fear. Civil practitioners must also be prepared to cope with tens of thousands of gas casualties, chemists must work at the discovery not only of new gases but of new antidotes, and every individual must have some instruction in the principles of self-protection against gas attack. So startling a vista rather took away the breath of members of the Section, but there was a brief discussion in which Colonel Fuller's views found some support. Lieut. Colonel P. A. Anderson agreed that in future wars, whatever physical implements might be evolved, they would be a means to a psychological end. This would necessitate a psychological test on enlistment to eliminate the neurotic and unstable. The selected material should be carefully looked after, comforts provided as far as possible, the limits of physical capacity studied, and personal cleanliness ensured. Group Commander Martin Flack thought that Colonel Fuller had reckoned without the Royal Air Force, but at the same time he admitted the truth of some of his contentions, and urged the very real need of providing on a large scale for public protection against aerial gas attacks, especially that a large and cheap supply of oxygen should be available and supervised by a competent authority. Major-General Sir William Macpherson was doubtful as to the truth of Colonel Fuller's forecast, and wondered what place in such warfare there could be for the fighting army, what weapons it would carry, and what would be the functions of its medical service. His own hope was in the limiting and regulating effect of international conventions. Colonel Fuller, in his reply, described such conventions as scraps of paper, and regarded it as quite a delusion to suppose that anything done at the Washington Conference could prevent the use of gas. Lieut. General Sir John Goodwin, who presided, said that he could not agree with Colonel Fuller in some respects, but it was a relief to him to think that he would no longer be Director-General of the Army Medical Service in the extraordinary situation which Colonel Fuller had developed.

#### AN ANTIVACCINATION MYTH.

AN old antivaccination myth is being amusingly revived by the method of parliamentary question. One of the new Labour members asked a question as to a statement by the Ministry of Health in its vaccination pamphlet, attributing the existence of compulsory revaccination laws in Germany to the year 1874, which laws, according to the questioner, had existed in Prussia since 1834. Sir William Joynton-Hicks replied that the pamphlet was correct, the Prussian law of 1835 referring only to soldiers in the army. As related to day by our Parliamentary correspondent (p. 483), the questioner subsequently returned to the charge, but apparently in a somewhat modified form, the question now being whether strict Prussian regulations dating from 1835 had not resulted in vaccination and revaccination of the overwhelming majority of the victims of the epidemic of the early seventies. To this the answer was that the regulations in question related only to houses in which small-pox existed, and that there were no penalties unless small-pox occurred. The story now revived seems to have had its origin in an effort by a prominent antivaccinationist nearly forty years ago to find some kind of rejoinder to the remarkable demonstration of the value of revaccination contained in the Report of the German Vaccination Commission of 1884. The diagrams relating to it were published in the *BRITISH MEDICAL JOURNAL* of 1885, vol. ii, p. 408 et seq., and the report formed the subject of a valuable paper read to the Epidemiological Society in December, 1885, by the late Dr. E. J. Edwardes. Perhaps the most interesting thing about the antivaccinationist's contention was its sheer audacity. It involved a flat denial of a statement by Dr. Boeing, a member of the German Commission who was opposed to compulsory vaccination; he said in the Report of the German Commission (p. 39), "Before 1874 we had no vaccination law in Prussia." Dr. Boeing also spoke of "the influence of revaccination which we have first from 1875."

The antivaccinationist's contention of nearly forty years ago involved also an assumption which would have been astounding had it not been preposterous. Holding as he did that the law dated from 1835, he cannot but have accepted the position that the German Government was doing practically an insane thing in appointing a Commission to investigate a law dating as from 1874, when the antivaccinationist supposed that the real date was 1835; that the Commissioners were equally insane in accepting such a reference and in publishing a great report on the basis of it; and that Germany and the whole civilized world have been none the less insane in accepting the report as a document having any relation to the facts. In short, the hypothesis that the revaccination law of Prussia dated from 1835, and not from 1874, was utterly wrong and ceased to require even contradiction; but after having been buried for decades it was exhumed in the parliamentary question which was asked on February 22nd. Notwithstanding that some effort has been made to cover the antivaccination retreat by speaking, in the later question, not of law but of regulations (of which the meagre scope and value was indicated in the parliamentary reply), we sympathize with the new M.P. whom the antivaccinationists have made the victim of the practical joke of putting into his mouth that question of February 22nd.

#### ALCOHOL IN ADOLESCENCE.

THE bill introduced by Lady Astor and read a second time in the House of Commons on March 9th is to a large extent the outcome of the efforts of primary school teachers, and the National Union of Teachers has passed a resolution in favour of the measure at its last two annual conferences. It has also had the support of the head masters and mistresses of several public and large secondary schools. It is practically the same bill as was introduced in the House of Lords, first by the late Lord Bryce, and afterwards by the Bishop of Oxford. It would make illegal the sale of intoxicating liquors to anyone apparently under 18 for consumption on licensed premises. As will be seen in the brief report in our Parliamentary columns the bill was passed in the House of Commons by a majority of 265 in a house of 405. It will, we believe, have the general approval of the medical profession, although, so far as we are aware, no overt action has been taken with the exception of a short manifesto issued on March 12th by Sir Thomas Barlow (formerly President of the Royal College of Physicians of London), Sir G. H. Makins (formerly President of the Royal College of Surgeons of England), Lord Dawson of Penn, and Sir Thomas Horder. They think that no valid objection can be raised against the bill, which can be considered quite apart from the principle of general prohibition. "There can be no doubt," they continue, "as to the desirability of employing all possible safeguards to prevent the danger of starting alcoholic habits in those who have just entered on the period of stress which puberty involves, and are on the threshold of adult life. Rapidly developing organs, new functions, and increased activities require all the protection that can be secured for them during that period, when readjustments of vital importance have to be made."

#### THE CENTENARY OF PASTEUR.

THE chief celebration in France of the centenary of Pasteur is yet to come. The culminating event will be the unveiling of a monument to him in the University of Strasbourg, where he was professor of chemistry from 1849 to 1854. The delegates attending the celebrations will assemble in Paris, and on May 25th will visit the tomb of Pasteur in the institute in Paris which bears his name. Later there will be a reception at the Sorbonne, and on the evening of the next day a reception at the Institut de France. On May 28th there will be a reception at the Hôtel de Ville, and on May 29th and 30th the delegates will visit Rheims and Verdun. The President of the Republic will visit Dôle on May 25th, Arbois

on May 27th, Besançon on May 28th, Mulhouse on May 29th, Colmar on May 30th, and will arrive at Strasbourg on May 31st. On June 1st he will unveil the monument, which is the work of the sculptor Larrivé. It is an obelisk 10 feet high, flanked by appropriate allegorical figures and bearing a medallion of Pasteur. In addition there is being erected at Strasbourg a permanent museum tracing the development of his scientific work through its various stages. A temporary collection will also be formed of apparatus and documents lent by Pasteur Institutes in Paris and elsewhere. An agricultural and industrial exhibition, illustrating the improvements which have resulted from Pasteur's work, will be open during the spring and summer, and there will be a series of congresses on tuberculosis, on child welfare, on maternity, and on cold storage. We have already reported the celebrations in Paris on the anniversary of his birth, and last week we published an illustrated account of the celebration at the Royal Society of Medicine in London on February 28th. There have been celebrations also in the United States and in many other countries. After that which took place in Brazil the Prefect of Rio de Janeiro directed that one of the main avenues of the city should bear Pasteur's name.

#### INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

THE first annual meeting of the International Society of Medical Hydrology was held at the house of the Royal Society of Medicine on March 8th, with Dr. Fortescue Fox, president for the year, in the chair. Members were present from Bath, Buxton, and Harrogate, as well as from France, Switzerland, and Czecho-Slovakia. A representative for Hungary was elected, making a total of eighteen countries represented; fifteen new members were also elected. A new rule was passed, widening the basis of membership in the society, to include all members of the medical profession interested in the subject. A letter from Professor Barduzzi of Siena was presented, advocating a more systematic teaching of hydrology. It was agreed to publish the *Archives of Medical Hydrology* (which are circulated in fifty-eight countries) three times in the current year. Dr. Ladislav Schmidt of Pistany, Czecho-Slovakia, read a paper by himself and Dr. Ed. Weisz on the use of hyperthermal radio-active mud as a method of home treatment.

THE officers of the Section of Medical Sociology have chosen "Mental Deficiency in its Social Aspects" as the subject for discussion in that Section during the Annual Meeting of the British Medical Association at Portsmouth next July.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Army Estimates.

##### THE ARMY MEDICAL SERVICE IN 1922.

IN the memorandum issued with the Army Estimates the Secretary of State for War makes the following reference to the Army Medical Service and the health of the army:

During the past year the number of patients in military hospitals in Great Britain has fallen from 2,348 to 1,770, and in Ireland from 1,055 to 139.

Hospital accommodation has been reduced to the extent of 1,700 beds in Great Britain and 1,770 beds in Ireland, the latter on the evacuation of troops from Southern Ireland. The military hospital at Chatham was closed in June last, and all sick of the military garrison there are now treated in the naval hospital, while at Gibraltar the naval hospital has been closed, and all naval sick there are treated in the military hospital, where the accommodation has had to be increased from 120 to 220 beds to enable this to be done.

The work of the Directorate of Pathology has made steady progress and the officers holding the appointments of assistant directors and deputy assistant directors of pathology in commands at home and abroad, who are in personal charge of the command laboratories, have made a number of valuable contributions to science. The precision of diagnosis so essential to successful treatment, and to all administrative measures directed to the

prevention and control of infectious disease, is largely dependent on the work of these officers, and has reached a very high standard of accuracy.

The health of the troops has been excellent. Infectious diseases have decreased considerably, and the state of vaccination, in spite of all difficulties, has been satisfactory. Although there has been considerable incidence of small-pox among the civil population, no cases occurred among the troops.

The medical aspect of recruiting has received constant attention throughout the year, ensuring a higher degree of efficiency in the preliminary examination of the recruit, and fewer discharges on medical grounds, with resulting economy.

#### The New Minister of Health.

Mr. Neville Chamberlain, the new Minister of Health, is generally considered to come to his office with special qualifications for dealing with the problems of public health and housing reform. Indeed, it is only in these circumstances that he could have been expected to give up the comparatively pleasant position of Postmaster-General for the charge of a department which, through the crisis of housing decontrol, has become perhaps the most perilous in the Government. Mr. Neville Chamberlain is a younger brother of Mr. Austen Chamberlain, and did not enter Parliament until a few years ago. Previously, however, he had, like his father before him, devoted much attention to the administration of social affairs in the city of Birmingham. To it was largely through his efforts, some ten years ago, that Parliamentary powers were obtained by the local authorities for dealing with the congestion of the population. Thus it was possible for the municipality to acquire land without stating its purpose, and to develop. Loans can be on a gradual scheme of mortgage, and a municipal bank can be established. As Lord Macaulay said, "Mr. Chamberlain proved himself a great man when he entered Parliament he was unfortunate in being called upon without notice and without resources to undertake the Ministry of National Service, an experimental Department which a very short experience showed to be unworkable for the purposes for which it was intended. Since then he has been quite content—until he was appointed, very recently, Postmaster-General—to be a private member, doing valuable quiet service on Grand Committees and in assisting the progress of several private bills. He is a clear speaker, but without any conspicuous rhetorical gifts. Indeed, it is rather as a business man with a keen interest in the betterment of mankind, disposed to move slowly and surely after obtaining thorough knowledge of facts, that he has distinguished himself.

#### Unemployment and Health.

Mr. Neville Chamberlain made his first speech as Minister of Health on March 8th, in replying to a debate on unemployment. He recognized that the prevalence of unemployment not only meant the infliction of great burdens and liabilities upon Boards of Guardians and the raising of rates of the local authorities with which his Department had to deal, but it affected also another function of the Ministry, that of improving the health of the people. He could not help thinking that the vital statistics of the last two or three years were a wonderful tribute to the work of the Ministry of Health and to the medical officers of health throughout the country. It might have been supposed that the results of unemployment would have been reflected in a great increase in the mortality rates, and especially in the infant mortality rates. Instead of that, all records had been broken in the opposite direction. It would, however, be a mistake to suppose that unemployment did not affect the health of the people. In particular it must affect the physique of the children. No one who had watched the children during the days of the war, when the working classes were earning high wages, could have failed to perceive the enormous improvements in their appearance and physique which were the results of the higher earnings of the period—improvements likely to be reflected in the future in a greater ability to resist disease. The Ministry of Health was vitally interested in the question of unemployment, and would with the Ministry of Labour do all it could to help forward schemes for its relief.

#### Sale of Intoxicating Liquor to Young Persons.

Lady Astor, on March 9th, moved the second reading of the bill introduced by her to make it illegal to sell intoxicating liquor to anyone apparently under 18 for consumption in a public-house. She mentioned that the bill was introduced previously in the other House by the Bishop of Oxford, and earlier by Lord Bryce at the instance of the teaching profession, which had the support of all organized women, including the National Council of Women, the National Women Citizens' Association, the heads of some of the great

public schools for boys and girls and of hundreds of elementary and secondary schools. They had also behind them some of the highest medical authorities. Lady Astor added that she had received 700 letters in support of it from women medical practitioners alone. As the law stood, a publican could sell beer to children over 14 for consumption inside a public-house as well as to be taken away. Spirits could be sold for consumption on licensed premises to young persons over 16. This bill, in limiting the age for sale for consumption, did not prevent young persons from fetching beer, neither did the bill touch clubs. The bill did not deal with treating. The whole of the colonies had this legislation, some making the restricted age higher. It was already adopted in Sweden, Norway, and Poland, and Lady Astor thought they had it in France. After debate for a full sitting, Lady Astor obtained the closure, and the second reading was carried by 335 votes to 70. The bill has been referred to Standing Committee C.

**Vaccination in Germany.**—Mr. Sullivan followed up the question he asked on February 22nd (BRITISH MEDICAL JOURNAL, March 3rd, p. 393) by another designed to indicate that the pamphlet on vaccination issued by the Ministry of Health was inaccurate. His question suggested that a decline in small-pox attributed in the pamphlet to a German Act of 1874 had then already taken place, and put forward the contention that, owing to strict Prussian regulations dating from 1835, the overwhelming majority of the sufferers in the great epidemic of 1871 had been vaccinated and revaccinated. Sir W. Joynton-Hicks, in reply, vindicated the accuracy of the pamphlet, stating that he was aware of the Prussian regulations referred to; that, according to a memorial prepared in the German Imperial Office of Health, and published in Berlin in 1896, those regulations provided for compulsory vaccination only in the event of an actual outbreak of small-pox in a house; that no penalties were provided for omission of vaccination when small-pox had not occurred; and that the total deaths from small-pox in the German Empire in 1871 and 1872 were officially stated to be 162,111. He had no information as to the total mortality in Prussia at that time, or as to the vaccinal condition of the cases, and referred Mr. Sullivan for further information to the evidence as to the Prussian regulations given by Dr. Arthur Hopkirk of Jena before the Royal Commission on Vaccination in 1889.

**Vaccination Debate.**—Dr. Watts, on March 6th, gave notice to call attention that day fortnight "to the serious danger which may arise owing to the lax manner in which the Vaccination Acts are at present administered, and to move a resolution." As, however, Dr. Watts has only fourth place on the Order Paper for that evening, it is unlikely that the subject will be reached.

**Insurance Committees.**—Sir W. Joynton-Hicks informed Dr. Watts, on March 7th, that there were 128 Insurance Committees in England, with an aggregate membership of 3,130. In 1922 the total expenditure on travelling was £2,065, and the payment for subsistence and loss of remunerative time was £1,658. The Insurance Act, 1921, reduced the minimum membership from 40 to 20 and the maximum from 80 to 40; the revised limits had not been in operation sufficiently long to indicate whether any further reduction in the size of the committees was practicable.

**Registrar-General's Report.**—Dr. F. E. Fremantle asked, on March 7th, if the Registrar-General's annual report for 1921, containing matter of first importance affecting the welfare of the people, would be presented to Parliament. Sir W. Joynton-Hicks with others, was now issued as instead of a command paper, but representation to Parliament, which was being arranged forthwith.

**Death Certificates.**—Dr. Chapple asked the Home Secretary, on March 8th, whether the City Coroner had said that doctors should not sign death certificates if they had seen the patient only for the first time two hours before death; whether instructions to this effect had been issued by the Department; and whether, in view of the fact that such a policy would greatly increase the number of inquests involving *post-mortem* examinations without adequate justification, he could state the average cost of such inquests. The Minister of Health (Mr. Neville Chamberlain) in a written reply said that no such instructions had been issued. He had no information as to cost of inquests involving *post-mortem* examinations, but would make inquiries.

**Pharmacy Bill.**—Mr. O'Grady, on March 8th, introduced a Pharmacy Bill "to regularize the position of all persons trading as chemists and druggists or pharmacy store proprietors in the sale of drugs, the dispensing of doctors' prescriptions and the sale of patent medicines." The measure was backed by Lieut.-Colonel Watts-Morgan, Mr. Tillet, and Mr. John Jones on behalf of the Labour party. The bill has since been printed. We propose to give some particulars in our next issue. As a private member's bill it seems to have little chance.

**Pensions Regional Headquarters at Nottingham.**—Replying to several members of Parliament, Captain Craig stated, on March 13th, that the Minister of Pensions, in view of the actual and prospective reductions in work, was considering economical modifications in administration. The minutes contemplated the transfer of the East Midlands Regional headquarters to Birmingham. This transfer would not cause inconvenience to pensioners, since it would not disturb the existing arrangements in that region for local area officers, medical boards, or treatment. Captain Craig added, as to the staff at the East Nottingham Regional head-

quarters, that the services of such members as were no longer required would be dispensed with gradually, reasonably long notice being given to individuals concerned.

**War Losses and Burdens.**—The Chancellor of the Exchequer has given particulars of British losses in men and money during the war. The particulars with regard to losses in men are as follows:

*British Empire Casualties.*

	Men enrolled.	Killed.	Wounded.
United Kingdom ...	6,211,427	743,702	1,673,262
Dominions and Colonies ...	1,655,527	140,523	357,785
India ...	1,679,416	61,338	70,833
Total ...	9,496,370	946,023	2,121,905

The expenditure from April 1st, 1914, to March 31st, 1919, was £9,590,000,000. Of this amount £1,820,000,000 was raised by direct and £910,000,000 by indirect taxation, and from other sources of revenue: £6,860,000,000 was raised by borrowing—£5,500,000,000 at home, and £1,360,000,000 abroad. War loans to allies amounted to £1,494,000,000, and to the dominions to £150,000,000. During the year 1922 the Dominions and Colonies have repaid £1,189,935.

**Small-pox in the British Army.**—On inquiry by Mr. Hancock, on March 8th, Lieut.-Colonel Guinness regretted that, owing to the volume of work involved, small-pox statistics of the British Army for the period from the outbreak of war were not yet available, but the figures for the preceding period were given, commissioned ranks not being included. The period dealt with is five and a half years from the beginning of 1909 until the middle of 1914. In the United Kingdom there were in that time neither deaths nor admissions from small-pox in a force of the average strength of 124,172. In India, with an average strength of 72,664, the admissions in the five and a half years were 66 and the deaths 5. In Egypt the average strength was 5,755, and the total small-pox admissions were 2, of which 1 was fatal. In the Colonies the corresponding figures were—strength 35,072, small-pox admissions 2, and deaths none.

**Medical Officers of the Ministry of Health.**—Mr. Neville Chamberlain stated, on March 12th, in answer to Mr. Short, that the number of medical officers now employed by the Ministry of Health is 56, and the salaries, including bonus, amount to £62,504. In addition, there are 35 regional medical officers employed whose salaries amount to £46,125, which sum is now recovered from the approved societies. In March, 1921, the medical staff of the Ministry, including the regional medical staff, was 101, whose salaries, including bonus, amounted to £130,630, the whole payable from Exchequer funds.

**Medical Officership for Hindley.**—Dr. Watts asked, on March 7th, whether the Minister of Health intended to sanction the appointment of a medical officer of health which was made by the urban district council of Hindley on January 15th last; if he was aware that although there were at least eleven applicants holding the diploma of public health the council selected an applicant who held no diploma nor had the minimum of experience which was laid down in the Sanitary Officers' Order of 1922 to meet the case of a medical officer of health who, although not having a diploma, had had practical experience of the duties of a medical officer of health. Sir W. Joynton-Hicks said the Minister was aware of the fact stated in the question, and had intimated to the Hindley urban district council that he was not prepared to approve their selection of a candidate not possessing the required qualifications. The council had been requested to consider the matter with a view to making a suitable appointment in accordance with the Sanitary Officers' Order, 1922.

**Death Rates in Mental Hospitals.**—Asked by Mr. Lansbury, on March 12th, as to the high death rate prevailing in the Powick Mental Asylum in certain years, Mr. Neville Chamberlain replied that the death rates for the years in question at Powick Mental Hospital were as follows (the rates for all county and borough mental hospitals in corresponding years are given in brackets): 1916, 11.2 per cent. (12.5); 1917, 22.7 per cent. (17.3); 1918, 32.6 per cent. (20.2); 1919, 12.7 per cent. (12.7); 1922, 6.7 per cent. (9.0). It would be seen, he said, that in only two years—that is, 1917 and 1918—were the rates higher than the mean for all asylums. The increase for those years caused much anxiety at the time; it was due to an outbreak of tuberculosis; the death rates from this cause in 1917 and 1918 were 74 and 162 per 1,000 of the population of the asylum. Two commissioners of the Board of Control made a special inquiry into the matter. They found that the outbreak was due mainly to two factors: (1) subnormal (war) feeding and (2) defective segregation, the result of overcrowding due to war conditions. It was satisfactory to note that by 1919 the death rate from all causes at Powick had drawn level with the mean for all asylums, and that in 1922 it was much below it.

*Answers in Brief.*

Mr. Neville Chamberlain has announced that the order as to special designations of milk will be reconsidered in consultation with the parties interested and reissued with the necessary amendments.

The number of persons, excluding casuals, who were being relieved in institutions provided by Poor Law authorities, was 214,000; and the number of beds in those institutions approximately 282,000.

The Ministry of Labour cost of living index number showed an increase of 80 per cent. over the pre-war level at November 1st, 1922, and of 77 per cent. at February 1st, 1923.

Sir W. Joynson-Hicks has stated that the residential accommodation for the treatment of tuberculosis under the schemes of local health authorities in England (which at present comprised upwards of 19,000 beds) had increased during the past two years by approximately 2,350 beds, while some thousand additional beds were in course of provision.

Of some six thousand medical men employed in the Pensions Department on boarding duties, only 299, or 5 per cent., had had no war service, and of these the large majority were specialists for whom no efficient ex-service substitute could be obtained.

## Canada.

### McGILL UNIVERSITY.

A CHANGE has been made in the length of session for medical students. The session of 1923-24 will start the beginning of the fourth week of September instead of in the first week of October. The entire medical course has been lengthened: the first two years will be spent in the Faculty of Arts, where a revised course, with special attention to languages, will be given; the following four years will be completely occupied with lectures and clinics in the Medical Faculty; and the seventh and last will be spent wholly in hospital. With reference to the two-year pre-medical course, the following extract from the minutes of the Faculty of Arts under the date of January 5th, 1923, will be interesting:

The Faculty considered the report of the conference between the B.A. Advisory and B.Sc. Advisory Committees of the Faculty of Arts and the Education Committee of the Faculty of Medicine. The following points were agreed upon:

1. That there would be no difficulty about the Faculty of Arts undertaking the proposed curriculum of the first year, though it was understood that this would probably involve additional instruction in mathematics, French, and Latin.

2. That the curriculum of the first of the two pre-medical years should be revised by the striking out of the words "including mechanics" after mathematics.

3. That in physics the first-year course should be the same as that given to the Arts students (three-hour course).

4. That additional instruction would be needed in chemistry, but that no additional instruction would be necessary in the department of physics and biology.

5. That the second year as well as the first should be under the control of the Faculty of Arts, but that there should be an advisory committee consisting of the professors giving the courses in biology, chemistry, and physics in the second year, the function of the committee being to keep the Faculty of Arts in touch with the views of the Faculty of Medicine in regard to the content of these courses.

### TORONTO UNIVERSITY.

Dr. Oskar Klotz, who graduated in medicine at McGill in 1906, and has recently been engaged in reorganizing the pathological department of the University of Buenos Aires under the direction of the Rockefeller Foundation, has been appointed to the chair of pathology in the University of Toronto, left vacant by the death of Dr. J. J. MacKenzie. Dr. Klotz, who was formerly a member of the teaching staff of the Medical Faculty of McGill University, became professor of pathology in the Rockefeller Institute in 1910, and was at one time director of the Magee Pathological Laboratory, Pittsburg.

### DEATH OF SIR THOMAS RODDICK.

Sir Thomas George Roddick died at his residence in Montreal on February 20th. By his death Canada loses one of its foremost surgeons. He graduated from the Medical Faculty of McGill University in 1868, and continued his connexion with the university in various capacities, as lecturer in hygiene, demonstrator in anatomy, professor of clinical surgery, Dean of the Faculty, and lastly as one of the governors of the university. Sir Thomas was the first colonial President of the British Medical Association, and presided over the Annual Meeting in Montreal in 1897. In 1896 he was elected to the House of Commons for St. Antoine division in Montreal, and held the seat until 1904. It was chiefly owing to him that the Canada Medical Act was finally passed in 1911; by this Act the Medical Council of Canada was formed, containing a representative from each province, with Sir Thomas as president. An obituary notice appears at page 489.

### MEDICAL COUNCIL OF CANADA.

Written examinations will be held in Toronto, Winnipeg, and Vancouver, beginning on June 12th, 1923. Applications for permission to write these examinations must be sent in to the registrar, Dr. Robert W. Powell, 180, Cooper Street, Ottawa, Ontario, not later than May 26th, 1923.

## Scotland.

INVESTIGATION ON THE RESULTS OF GASTRO-ENTEROSTOMY. The Scottish Committee of the British Medical Association recently appointed a special committee to inquire into the results following the operations of gastrectomy and gastro-enterostomy. Local committees are also in process of formation at the four university centres in Scotland with the view of collecting statistics of these operations. A schedule has been drawn up containing two pages of the headings under which information is desired, and this should greatly facilitate the setting down briefly of details from the records of cases. Copies of the schedule will be issued shortly to hospital surgeons and others willing to co-operate in the inquiry, and at a later stage, in cases where complete histories are not on record, efforts will be made to complete them by communicating with the medical attendant. It is hoped that the inquiry may be conducted on a wide basis, and it ought to be feasible to get from Scottish statistics the records in at least 5,000 cases of these operations. The results of such an investigation should be of very great value to medical opinion and practice.

### NEW EDINBURGH HOSPITAL BUILDINGS.

The plans have now been passed for a new maternity hospital to be erected by the trustees of the hospice facing the King's Park. This hospital will form the Dr. Elsie Inglis War Memorial, and will cost approximately £30,000. A laboratory and x-ray block for the branch of the Royal Victoria Hospital for Tuberculosis at Liberton has also been approved. It is intended that research work on tuberculosis shall be carried out here; the cost of the building, irrespective of apparatus and fittings, will be about £6,000.

### GLASGOW ROYAL INFIRMARY CLUB.

The annual business meeting and dinner of this club was held on the evening of March 9th, in Ferguson and Forrester's, Buchanan Street. Mr. Henry Rutherford presided over a very representative gathering of about sixty members. The toast of the evening, "The Royal Infirmary," was given from the chair, and was responded to by Mr. J. Hogarth Pringle. "Past and Present Residents" was proposed by Dr. John Henderson, and the respective replies were made by Drs. John F. Fergus and Paton Neilson. The toast of "The Chairman" was given by Mr. Thomas Kay, and Mr. Rutherford suitably replied. The enjoyment of the evening was greatly enhanced by songs from Drs. William Scott, W. A. Sewell, O. H. Mavor, and George Dalziel, and humorous recitations by Drs. Adam Patrick, John F. Fergus, and W. A. Sewell. Mr. R. H. Parry was appointed chairman for next year, and Drs. W. A. Sewell and J. K. Rennie were appointed joint secretaries and treasurers. During the evening, as in former years, a collection was made for the Royal Medical Benevolent Fund, and a sum of over £5 was forwarded to the British Medical Association for transmission to the Fund.

## England and Wales.

### LEICESTER NEW HEALTH OFFICES.

THE new public health offices of Leicester were opened on March 9th by Sir George Newman, Principal Medical Officer to the Ministry of Health. In acknowledging the great amount of useful and enduring work that Dr. Millard and Dr. Warner had done for Leicester, Sir George Newman said that in the last forty years the death rate of Leicester had been reduced from 21 to 12 and infant mortality from 201 to about 86. Every child born in Leicester to-day had twelve years more expectation of life than its grandparents. The invalidity which was endured by suffering humanity had been reduced, and the total capacity and happiness of the citizens had been increased. Compared with forty years ago, there was now a totally new conception and a larger and more splendid vision of what the health of the nation really meant. Dr. Millard's report had spoken of the new and hopeful spirit of preventive medicine, and Sir George Newman pointed out that that was not the monopoly of the public health services, but the opportunity of all medical and voluntary services. In the new health

offices the sanitary inspector's office and the tuberculosis consulting and waiting rooms are on the ground floor; on the first floor are the offices of the medical officer of health, the tuberculosis officer, and others; on the second floor are the office of the infant welfare medical officer and the offices of the health visitors; the third floor has not yet been fitted up, but it is suggested that it should be used for chemical and bacteriological laboratories. Hitherto the tuberculosis department has been carried on in separate premises.

#### MANCHESTER MEDICAL OFFICER OF HEALTH.

To meet the new medical officer of health of Manchester, Dr. R. Veitch Clark, over two hundred medical practitioners of Manchester assembled in the Lord Mayor's parlour at the Town Hall on February 28th. Invitations had been sent out to all the practitioners of Manchester, but professional duties kept a number away. The Lord Mayor, in introducing Dr. Clark, described the occasion as a unique gathering of the medical profession in Manchester, designed to provide a link between the new medical officer of health and the medical profession generally. Dr. Clark said that there was nothing more fundamental to the success of modern preventive medicine than whole-hearted friendship and co-operation between the administrative branch of the medical profession in the city and those who practised among the citizens. His ideas as medical officer of health would not be revolutionary. He felt very strongly that the primary function of the department for which he was responsible was one of prevention. In working together whole-heartedly the medical profession was following on the lines which would in the end produce the greatest benefit to the public, and was also acting in its own best interests.

#### A SPA TREATMENT ESTABLISHMENT AT LLANDRINDOD.

The Priory for Wales of the Order of St. John of Jerusalem has opened a Spa Treatment Establishment at Llandrindod Wells for disabled ex-service men under the Ministry of Pensions, and also for the civil community. The object is to place the waters and balneological equipment of this famous Welsh spa at the disposal of those who are unable to bear the expenses such treatment ordinarily entails. Llandrindod is frequented particularly by patients suffering from rheumatic and gouty conditions, neuritis, colitis, obesity, skin disorders, diseases of the gastro-intestinal system (especially following residence in tropical climates), dyspepsia, and debility. Cases of infection or of an incurable nature will not be accepted at the establishment. The patient will pay an inclusive fee, which will cover board, residence, and all other necessary expenses for the complete course of treatment. Full particulars may be obtained from the secretary of the establishment. It is stated also that the Priory for Wales is negotiating with the Admiralty for the taking over of the Royal Naval Hospital, Pembroke Dock, for ex-service men in the counties of Pembroke, Cardigan, and Carnarvon.

## Ireland.

#### CITY OF LIMERICK MEDICAL ASSOCIATION.

At a recent meeting of the City of Limerick Medical Association, which consists of members of the British and Irish Medical Associations as well as members of other medical bodies, the annual report of the activities of the association was read. For many years it has been known that the medical profession in Limerick is the best organized in Ireland. The secretary, Dr. W. J. O'Sullivan, sets out in the report the chief achievements of the Limerick Association; they show clearly what organization can do. The most notable is perhaps the fact that ten of the principal life assurance companies operating in Ireland pay two guineas for medical examination in life policies. In Dublin and Belfast the fee paid to medical practitioners for the same work is one guinea. Another instance is that medical referees under the National Insurance Act are paid at the rate of two guineas for each case examined. In this respect it may be mentioned that there are no whole-time medical referees under the Insurance Act as it applies to Ireland. There is, however, a fund, under the control of the Irish Insurance Commission, out of which fees are paid to medical practitioners who are called in to give second

opinions. The report gives also a list of the correspondence which took place during the year, and includes letters addressed to Dr. Philip Leo (Cork), Dr. Honnessy (Irish Medical Secretary, British Medical Association), the Secretary of the Child Welfare Scheme, and others.

#### POOR LAW OFFICERS' SALARIES.

The Lurgan Guardians recently considered a communication from the Ministry of Home Affairs, Northern Ireland, relative to the salaries of the medical officers of the union. This was in reply to a copy of a petition forwarded by Dr. J. S. Darling, medical officer of the workhouse (on behalf of the medical union staff). The Ministry told the Guardians that careful consideration should be given to the salaries of the medical officers of the union, that these could not be regarded as other than inadequate, and not in proportion to what had been considered in the great majority of the unions in Northern Ireland fair and reasonable for medical officers, and that the Guardians should take steps to grant an improved scale of salaries. The matter was referred to the Finance Committee to deal with and report to the Board.

## Correspondence.

#### THE DANGEROUS DRUGS REGULATIONS.

SIR,—A point in the Dangerous Drugs Regulations, which seems to have escaped notice in the recent correspondence in the JOURNAL, appears to me to require careful consideration.

In the Memorandum of the Home Office published on page 69 of the JOURNAL of January 13th, paragraph 6 authorizes a practitioner to be in possession of the drugs, "so far as is necessary for the practice of his profession," and the letter of Sir Malcolm Delevingne on page 73 of the SUPPLEMENT of March 3rd at the end of the penultimate paragraph states: "A duly qualified medical practitioner is a person authorized . . . to be in possession of the drugs so far as is necessary for the practice of his profession, and he can therefore—if in practice—buy the drugs. . . ."

The words "if in practice" are being interpreted by the chemists in such a manner that whole-time administrative medical officers in the public health service cannot obtain any of the drugs even in emergency, since their work, being largely administrative, is not considered by the pharmacists as practice.

Surely a retired or a full-time medical officer, if called to a patient in emergency, is in practice just as much as the medical man who, having put up a name-plate, is called to his first patient. Is the last to be prevented from having a supply to use in emergency, since he is obviously not in practice until he is called to a patient?

I am of opinion that the Home Office having drafted the Regulations to deal with a very small class of practitioner—namely, the "dope fiend"—has forgotten the elements of logic, a first principle of which is "a particular ad universale non valet consequentia."—I am, etc.,

Wolverhampton, March 15th.

H. CARTER MACTIER, M.B.E.

SIR,—I have to thank Mr. E. B. Turner, Chairman of the Medico-Political Committee, British Medical Association, for his courteous, full, free, and frank statement in your issue of February 17th. I fully recognize the work done by the Committee. Mr. Turner states "while this meeting was in progress a message was brought in from the Home Secretary announcing that he had decided to appoint a Select Committee as requested. As a result of the deliberations of this body the regulations were reintroduced in a very much more satisfactory form, to which no objection was taken by the Council of the Association." The italics are mine. It is clear from this that the Council of the Association did not object to the regulations as they are while they still considered them objectionable. It is clear that they compromised with the political dialecticians on a matter of principle. Most of us have no objection to compromise on matters of detail; but we should never compromise on matters of principle. We should say to the Home Secretary, "No, you pass the regulations, in spite of our refusal, to agree, and accept the responsibility. We are responsible to ourselves and to the profession, and we decline to accept a shadow of responsibility for regulations which we do not fully approve."

About these regulations the politicians can and of course do tell us that they were passed after the profession had endorsed them, and what can we say but admit the fact? It is time for the profession to wake up and see to their interests and to their independence in these days when communistic legislation is invading every sphere of human action.—I am, etc.,

HENRY SMITH, C.I.E., Lieut.-Col. I.M.S.(ret.).

Sidecup, Feb. 27th.

SIR,—The reply of the Assistant Under Secretary of State, Home Office, regarding the "Dangerous Drugs Regulations," noted in the SUPPLEMENT of March 3rd, suggests that the new regulation was actually framed against all medical men who have retired from practice, so that no retired medical man can keep in his house a small quantity of laudanum, or a pocket case of hypodermic drugs for a sudden emergency. Yet the retirement of a doctor does not preclude him from being called up by any case of sudden illness or accident occurring in his immediate neighbourhood; for we all know that in a case of life and death time is of the utmost importance, and the nearest medical aid will be sought.

It is also a disgrace and a slur on the retired medical men that they are considered utterly unfit to keep a few anodynes in their house; after practising their profession for thirty or forty years they are, when retired, to be looked upon as victims of the drug habit.

I think the Medico-Political Committee might try and get an amendment in the regulations, or a special permission obtained from the Home Office that a retired medical man may be in possession of a small quantity of anodynes for emergencies.—I am, etc.,

H. D. J.

March 12th.

This matter is referred to in an article at page 477, and in a Current Note in the SUPPLEMENT.

#### DR. HALDANE'S CONCEPTIONS OF BIOLOGY.

SIR,—In your issue of March 10th (p. 441) "C. A." asks whether I might not with advantage have substituted the words "machine" or "machinery" and "mechanical" for "mechanism" and "mechanistic." I think, however, that there is justification for the latter words. When we speak of the "mechanism" of a steam engine or a kidney we mean not only the machinery but also the manner in which it works; and a "mechanistic" theory of renal secretion is a theory that renal secretion is the outcome of mechanism.

I must admit that the word "environment" used by me is clumsy. The French "milieu," as used by Claude Bernard, is much superior; but I have had to accept what ordinary English usage has given me. The only alternative word seemed to be "medium." I feel sure that this would not satisfy "C. A." any more than it does me.

To the deeper questions raised in the letter of "C. A." I shall not attempt to reply here; but it may be of interest to those who wish to know my opinions that I have attempted to discuss some of these questions in an article on "Natural Science and Religion" in the forthcoming number of the *Hibbert Journal*.—I am, etc.,

J. S. HALDANE.

Oxford, March 11th.

#### PSYCHOLOGY AND MEDICINE.

SIR,—The address on Psychology and Medicine by Sir Frederick Mott published in the last number of your JOURNAL is not only admirable for its wisdom, clarity, and diction, but is most stimulating and suggestive in many directions.

His allusion to Lucretius—and he might have added Stegnois of Megara, Plato, and Aristotle—seems to point the moral that the brotherhood of medicine and psychology should, in these days, also include sociology.

The laws of heredity in their bearing upon the causation of the various psychoses and degrees of feeble-mindedness, apart from certifiable insanity, surely demonstrate that they have an intimate and practical connexion with the well-being of society and the maintenance of the quality of our race. It is remarkable that medicine has hitherto shown no apparent recognition of this connexion, has given no lead to the legislature and to the public by demonstrating it, no warning as to the possible or even probable danger of ignoring it.

It would be most interesting if Sir Frederick Mott could tell us whether he is apprehensive, for instance, about the differential birth rate in this country between the intelligent

and capable normals and the unintelligent lower grade morons; whether our statistics show any resemblance to the American Army figures of Yerkes; whether he thinks that as modern civilization has with the help of scientific medicine inhibited the effect of natural selection, we should try to build up some form of rational selection as a substitute; whether in fact our system of segregation should include others, in addition to certified cases, so as to preserve the quality of our race and anticipate a tendency towards fatal deterioration.—I am, etc.,

Brighton, March 11th.

ROBERT SANDERSON.

#### HOSPITAL POLICY.

SIR,—The chairman of the Hospitals Committee has devoted a long letter to a claim of wonderful foresight on the part of the British Medical Association in that the Hospitals Commission has adopted its definition of a voluntary hospital. Surely it was obvious to the man in the street that the so-called voluntary hospitals had, by force of circumstances, changed their character: that while originally instituted and supported by voluntary contributions (hence the title), they were no longer able to pay their way as charities, and were compelled to accept payment from patients who, either directly or indirectly, were able to pay for treatment.

The new meaning attached to the word "voluntary" is merely camouflage, which does not hide the fact that the hospitals have become an increasing factor in competition with private practice, both general and specialist. If the British Medical Association has not deliberately shut its eyes to this fact, it is its duty to discuss it openly, instead of wasting its time finding a definition which will save the faces of those who are willing to exploit the profession. The hospitals are now using the old weapon of contract practice, which in the past has proved so deadly to medical prestige, and it will require more than "voluntary management" to protect the profession from its insidious effect. For instance, it is stated that approved societies are ready with £200,000 a year for the hospitals. No one can help being pleased to hear this, but has anyone asked how much of that sum will go to the doctors who do the work?

The only rational policy for the British Medical Association is to draw a sharp distinction between work done for charity and work which can be paid for, and apply to the latter the cardinal principles which were the watchword of the Association at the institution of the Insurance Act. If it fails to do this the result may well be disastrous. I hope I shall not be able to write, "I told you so."—I am, etc.,

J. C. TURNBULL.

Bury, Lancs, March 11th.

SIR,—I wonder if Mr. Bishop Harman or anyone else would enlighten your readers about the supposed wonderful virtues of the "independent and voluntary management" of our hospitals. What do they mean by it?

Take an ordinary provincial hospital. Its board of management is elected by the subscribers at the annual meeting, and is responsible to them, just as members of a town council are elected by and are responsible to the ratepayers. Of course, the one has life vice-presidents, who have perhaps subscribed a hundred guineas, and the other has aldermen. The hospital has its paid secretary. The town council has its paid town clerk. Both have their staffs of paid employees, only the council pays its employees better and their hours of work are more humane. It is a hundred to one that most of the members of the board of management are in other capacities elected representatives of the people—for example, town councillors, or county councillors, etc. The medical profession will be represented by certain representatives of the medical board, small in number but great in influence.

Now I want someone to explain to me what would be the difference if the hospitals were financed more or less by the State or municipality, and the hospital board of management consisted of such a body as that which has been elected to distribute the Government subsidy. Personally, I do not care a straw how the hospitals are financed, as long as it is done economically and efficiently, which no one can say is the case at present. As a member of the medical profession, I am keenly interested in preserving the status of the profession, in seeing that it is adequately remunerated, and that every member of the profession should have a fair and equal chance of becoming a member of a hospital staff; and, further, that those members of the profession who are not

on hospital staffs shall have every facility offered to them to preserve their familiarity with hospital work and with every advance in professional knowledge.—I am, etc.,

Helston, March 12th.

FERDINAND REES.

Sir,—May I encroach on your space in order to congratulate Dr. John Fletcher upon his excellent letter appearing in your issue of March 3rd? After a protracted series of controversial letters and addresses written and delivered upon a bewildering number of side issues, a statesmanlike view of the problem in its entirety and a sincere attempt to point a broad path to its solution are more than welcome, and are in themselves a reproach to querulous bickerings on such matters as "staff funds" and "maintenance costs."

The main point of a "hospital policy" surely must be to keep the hospitals open. Only second to that comes the duty of improving them. We find, as a matter of fact, many hospitals struggling under a crushing debt, and a few which have actually had to curtail the number of beds, and that even this position is only achieved after special appeals, lotteries, and competitions. The most discouraging consideration of all is that even by keeping open a fixed number of beds a hospital is in reality fighting a losing battle since an ever-increasing population demands a corresponding increase of hospital accommodation. As for the secondary duty of improving hospitals, he would be a bold man who talked to the average committee these days about improvements.

The question is purely one of finance. If voluntary subscribers cannot, or will not, shoulder the financial burden involved by the normal steady growth of hospitals, then what remains? Who else can shoulder it if not the State? Surely it is our duty to press before the public the fact that there is at least a very grave possibility of a generally enfeebled hospital service if the present financial system is carried on unaided, and also to endeavour to formulate an alternative scheme.

It is certain that sooner or later we shall have a Government with views and aims differing from those of the present administration, and probably with ideas of its own on the subject of hospitals. Those views on general principles will probably take the line of "so many people, so many beds, so many doctors." Surely it would be only the most common prudence to formulate a scheme, in advance of such a day, for the common help and guidance of Government and profession.

Many doctors propound a baffling proposition that State aid for a hospital would immediately cause a peculiar form of cerebral atrophy in the staff, resulting in the loss of all desire for doing good and original work, both clinical and pathological. Especially do they fear a complete loss of "initiative." All the evidence is happily against such a state of affairs. During the war magnificent work, both individual and co-ordinated, was performed by a profession working directly for the State. Within the last few years tropical medicine has been converted from a sort of chaotic mythology into a science, mainly by the labours of gentlemen in public employ. Our public health service is respected throughout the world, and, again, is staffed by public servants. The recently opened Maudsley Hospital is to be supported mainly by public money, but nevertheless was widely welcomed as an institution certain to be of great value. The list could be extended indefinitely.—I am, etc.,

March 7th.

JUNIOR.

#### BRITISH SPAS: THE NEED OF SCIENTIFIC CO-ORDINATION.

Sir,—Six years ago, in a lecture before the Royal Society of Arts, one of us ventured to point out what he conceived to be the promising possibilities of British hydrology, if the resources of our country were organized in a scientific spirit, and if this department of medical knowledge were given academic recognition.

At present both those who provide and those who carry out the various methods of treatment at the British spas have an exceptionally difficult task to perform, because they are to a large extent isolated. We do not perhaps realize what a wealth of material, how much time and thought and money, what persevering energy and devotion go to the making of a modern spa; and, on the scientific side, what careful study of methods of treatment is required in the most difficult class of cases and, above all, what alertness to new impressions and new knowledge. Recent years have increased all these demands.

There is now happily in some quarters a unifying leaven at work. It is recognized that rivalries and jealousies are a gratuitous aggravation of difficulty and block the way of progress. It is becoming evident that there can be no real rivalry between the British spas because each of them is endowed with waters and climate of a different type. For this reason the proper development of each spa must follow individual lines. When this natural differentiation has been agreed and worked out a great step will have been taken in the history of British waters.

The British Spa Federation has made a fine beginning in the work of co-ordination on the business side. Representatives of the principal spas are now brought together in periodical meetings, with authority to deal with many problems of a technical and business character, and of course a united propaganda. Those who know something of the hard work that has been devoted to this patriotic effort must wish it complete success. Undoubtedly without an enlightened policy of this kind the actual treatment, which is, of course, more interesting to medical men, would now be difficult to carry on.

On the scientific side there is as yet no unifying or co-ordinating influence at work. We stand exactly where we did six, or for that matter sixty, years ago. One sees praiseworthy but isolated endeavours by spa practitioners to perfect themselves in the branch of medicine in which they are engaged. One even sees here and there unassisted efforts at research into the action of waters and baths, but nowhere an organization for study or instruction. And yet if an art is to be practised, surely it should be taught. What can be the future of the spas if the young scientifically minded medical man is not attracted to them? The scientist at the spa cannot be dispensed with. How little do our senior students and junior graduates know of the wealth of opportunity awaiting them in the study and use of physical methods of treatment—for example, of the astonishing effect of external treatment in chronic disease, of the fascinating study of the manifold reactions aroused in the body by physical agencies? And again, in the present absence of teaching, what can the physician or the general practitioner know of the principles of medical hydrology and of their practical application in England, that he should prescribe a course of waters to his patients? Here, as elsewhere, he must understand the value of treatment before he can recommend it.

It may be said that such matters belong to the post-graduate period. But it may fairly be claimed that those who wish to make a study of medicinal waters and baths should have the means of doing so both before and after graduation. In France, Italy, and Germany every year, with official and academic authority, study tours—often following a systematic course of lectures—are planned to the chief spas, where interesting discourses and demonstrations are arranged. To the medical youth in these countries is thus given an opportunity of a personal study of the accepted methods of treatment by waters and baths. The new generation begins where the old leaves off, and both science and practice are assured of an orderly progress. Many older practitioners also avail themselves of these study tours.

In England none of the proposals that have been put forward during the last twenty-six years to initiate a similar teaching of medical hydrology have as yet borne fruit, the latest and most serious proposal in 1914 being held up on account of the war. Now that men's minds are again seriously considering the problems of peace, perhaps this matter also may be dealt with. Will the Ministry of Health and the medical schools, in the public interest and in the interest of science, accept any responsibility for the medical use of waters and climates? Upon the answer to this question will depend, *inter alia*, the scientific development and the efficiency of the British spas.—We are, etc.,

R. FORTESCUE FOX,

President of the International Society of Medical Hydrology;

J. CAMPBELL McCLELLAN,

President of the Section of Balneology and Climatology of the Royal Society of Medicine.

London, W., March 7th.

#### IONIC MEDICATION.

Sir,—In your issue of March 10th. (p. 409) there is a paper by Dr. David Campbell, giving his opinions as a result of a serious attempt to estimate the value of ionization treatment. Since he makes several quotations from my small book may I be allowed to allude to a few points. He thinks there is no evidence for "lytic action." The experiment I saw in

Professor Leduc's laboratory and described and illustrated in my book proves that a continuous current causes a transfer of water from the positive to the negative electrode. Increase of water means increased solution, and this is the explanation of "lytic action" under the negative electrode. To assess the value of this in treatment one would select cases in which lytic action would be beneficial and in which the result could be easily confirmed, and avoid choosing cases in which the pathological conditions were problematical, and in which physical conditions, such as depth, militated against ionic exchanges or hydration taking place at the spot desired. Under the former heading we can place the thickening which follows sprains or injury to a superficial joint, such as the ankle, knee, or wrist, as well as cicatrices causing limitation of movement. In these cases there is ample clinical evidence to confirm the benefit claimed for ionization treatment. Instead of selecting cases in which the nature of the lesion is evident and in which the result is decisive Dr. Campbell has elected to draw his conclusions from cases in which the premisses, so to speak, are not clear.

With a good deal of what he says about the penetration of ions I agree, but I do not think he is justified in saying that ions introduced electrically present no differences in effect from a solution of a salt given by hypodermic injection. He describes the physiological effect on distant organs, such as the brain, as following both methods, but it must be remembered that ionization is usually practised for its local effect. When a hypodermic injection is given there is no reason to believe that in all cases the local cells of the tissues, as distinct from the lymph around them, are penetrated by the salt, whereas when ions are introduced electrically it is believed that both cells and intercellular fluid are penetrated. There is also an exchange of ions between the cells and the fluids of the tissues at a greater depth than that to which the great majority of introduced ions have penetrated. This exchange of normal ions between cells and fluids in apposition is a paraphrase for the word "nutrition." The skin is the great sense organ, abundantly supplied with nerves. Even without penetrating beneath the skin there is a wide field for the introduction of soothing ions, such as the salicyl ion, into the terminations of the nerves in neuralgias, and also in those superficial pains in which the seat of the disease can only be acted upon reflexly.

Dr. Campbell says he has no practical experience of ionization for surgical cases, but he makes some theoretical statements about the mode of action of zinc ionization with which I cannot agree. One striking result of zinc ionization for sepsis is the rapid subsidence of inflammation.—I am, etc.,

A. R. FRIEL.

London, W.1, March 13th.

## BLIND MASSEURS.

SIR,—I am very interested in the work of the Association of Certificated Blind Masseurs, of which I have the pleasure to be President. It has recently published leaflets giving the addresses of its members in London and all parts of the British Isles. May I venture to suggest that all registered medical practitioners should obtain copies from the secretary of the Association, 224 6-8, Great Portland Street, London, W.1?

These leaflets show that members of the Association, both masseurs and masseuses, are established in practically all the large towns, as well as in all parts of London and the suburbs. As massage is work which, it is generally recognized, can be most efficiently carried out by blind people properly trained, those doctors who can see their way to the employment of the members of the Association of Certificated Blind Masseurs will be aiding in a work of national importance.—I am, etc.,

ROBERT JONES.

Liverpool, March 8th.

## MEDICAL AXIOMS AND APHORISMS.

SIR,—Permit me an observation on your friendly review of my *Medical Axioms, Aphorisms, and Clinical Memoranda*. It did not occur to me that unsung axioms and aphorisms would necessarily be regarded as my own composition. Some of them are part of the common heritage and tradition of medicine. Their authorship would be difficult, or perhaps impossible, to determine.

In every case where the author is known to me his name was appended.—I am, etc.,

J. A. LINDSAY.

Belfast, March 12th.

## Universities and Colleges.

## UNIVERSITY OF CAMBRIDGE.

MR. M. B. R. SWANN, M.A., M.B., who since 1920 has been University Demonstrator in Pathology, has been elected to a corporate Fellowship at Gonville and Caius College, and appointed a lecturer.

## UNIVERSITY OF LONDON.

THE regulations in the Faculty of Medicine for internal students have been amended by the addition of the following after the word "physiology" in line 2, paragraph 4, section IV, on page 240 of the Red Book, 1922-23: "or the B.Sc. Honours Examination in Physiology."

Sir William Collins has been reappointed the representative of the London County Council on the Senate for the period 1923-27.

The ceremony of Pre-entation Day will take place in the Albert Hall on Thursday, May 3rd, and not Wednesday, May 2nd, as stated in the University Calendar (White Book).

Applications for grants from the Dixon Fund for assisting scientific investigations must be sent in between April 1st and May 15th, and for the Thomas Smythe Hughes Medical Research Fund for assisting original medical research between May 1st and June 15th. Further particulars may be obtained from the Academic Registrar.

## UNIVERSITY OF SHEFFIELD.

THE Council at its meeting on March 9th made the following appointments: Mr. G. Grant Allan, M.B., Ch.B., D.P.H. (Edin.), to the post of Assistant Bacteriologist; Miss Clara D. Tingle, M.B., Ch.B. (Shef.), to a Demonstratorship in Pathology.

## UNIVERSITY OF DUBLIN.

## TRINITY COLLEGE.

THE University of Dublin, on March 12th, conferred the honorary degree of M.D. upon Dr. William James Mayo, the well known surgeon of Rochester, U.S.A., and Professor E. H. Tweedy, gynaecologist to the Royal City of Dublin Hospital.

## ROYAL COLLEGE OF SURGEONS OF ENGLAND.

## Council Election.

THE Secretary of the College of Surgeons has sent out the usual announcement, which on this occasion informs the Fellows of the College that a meeting will be held at the College on Thursday, July 5th, at 2 p.m., for the election of four Fellows into the Council in the vacancies occasioned by the death of Sir Charles Ryall, by the retirement in rotation of Sir Charters J. Symonds, K.B.E., C.B., and Sir Herbert F. Waterhouse, and by the resignation of Mr. F. F. Burghard, C.B. Blank forms of the requisite notice from a candidate and of his nomination may be obtained on application to the Secretary, and the same must be received by him, not later than on Monday, March 19th. A voting paper will be sent by post to each Fellow whose address is registered at the College, on Tuesday, April 3rd. Had Sir Charles Ryall lived he would have had to retire in rotation, having been elected on the Council, like Sir Charters J. Symonds and Sir Herbert Waterhouse, in 1915. Mr. Burghard having been elected in 1921, the candidate who comes out fourth on the poll will be substitute member until 1929.

## The Services.

## DEATHS IN THE SERVICES.

Deputy Inspector-General Alfred Gideon Delmege, M.V.O., K.H.S., R.N. (retired), died at Blackheath on February 2nd, aged 76. He was the son of the late Julius Delmege of Rathkena, co. Limerick. He graduated M.D. in the Queen's University, Ireland, in 1868, and took the L.R.C.S.I. in the same year. He entered the navy as assistant surgeon in 1859, became fleet surgeon in 1889, and retired ten years later, with an honorary step of rank, as D.I.G. He served in the Ashanti war of 1873-74, going out with the first detachment of Royal Marines sent to Cape Coast Castle, and received the medal, also the thanks of the Admiralty for his services. In 1879-82 he served on H.M.S. *Bacchante* during the voyage round the world made by Princes Albert Victor and George during these years. From 1887 to 1899 he served on the Royal yacht *Osborne*. He was awarded the M.V.O. for his services as medical attendant to the Prince of Wales, the present King, during his illness in 1893, and was appointed Honorary Surgeon to the Prince of Wales in 1899, and subsequently Honorary Surgeon to King Edward VII. In 1884 he married Mary Elizabeth, daughter of the late Right Hon. James Anthony Lawson, by whom he had two sons.

Lieutenant-Colonel Herbert Stockley Taylor, R.A.M.C., died at Kampti, in the Central Provinces of India, on November 17th, 1922, aged 53. He was born on July 21st, 1863, and educated at University College, London, taking the M.R.C.S. and L.R.C.P. (Lond.) in 1895. After filling the post of senior house-surgeon of the Clayton Hospital, Wakefield, he entered the R.A.M.C. as lieutenant on January 29th, 1899, becoming major after twelve years' service, and became lieutenant-colonel in 1915. He served in West Africa in 1901, in the expedition up the Gambia river, receiving the African general service medal with a clasp, and also in the recent great war.

## Obituary.

SIR THOMAS RODDICK, M.D., F.R.C.S.,

Formerly Professor of Surgery, McGill University; Ex-President of the British Medical Association.

SIR THOMAS RODDICK, who, as briefly announced last week, died on February 20th, was President of the British Medical Association on the first occasion on which it held its Annual Meeting outside the British Isles; this was in 1897, and it was largely through Roddick's influence that the invitation was given and accepted. He held a position of great prominence in the profession in Canada at the time, being professor of surgery in McGill University, Montreal, and a member of the Canadian Parliament. He came over here in the winter of 1896, and his genial presence, force of character, and ready speech at once made him many friends in the Association and paved the way for the success of the Montreal meeting.

Sir Thomas Roddick, who received the honour of knighthood in 1914, had been in failing health for several years; he had been in the habit of spending each winter in the more genial climate of Florida, but this year did not make the journey, and died in his house in Montreal.

Thomas George Roddick was the son of the principal of the Government Grammar School at Harbour Grace, Newfoundland, and was born there on July 31st, 1846. He entered McGill University, Montreal, in 1864, and was the first student of his year, taking the Holmes gold medal. On the completion of his curriculum he entered the General Hospital, and acted as resident surgeon for six years. In 1874 he became demonstrator of anatomy in McGill University, and attending surgeon at the General Hospital; in 1875 he was appointed to the chair of clinical surgery. At the outbreak of the North-West rebellion in 1885 he was appointed deputy surgeon-general to the militia of Canada, and went to the front to organize the medical service and to make all necessary arrangements with regard to hospitals. In 1890 he succeeded Dr. Fenwick in the chair of surgery at McGill University, and upon the erection of the Royal Victoria Hospital, through the munificence of two Montreal citizens—Lord Mount Stephen and Sir Donald Smith (afterwards Lord Strathcona)—he was entrusted with the organization and equipment of the surgical department, and visited all the great European centres in that capacity. In 1893 he became full surgeon and in 1896 consulting surgeon to this hospital. For many years he was chairman of the medical board of the hospital, was Dean of the McGill Faculty of Medicine from 1901 to 1908, and was subsequently appointed a governor of the University.

His distinction as a surgeon was widely recognized, not only in Canada, but also in this country; he was elected an Honorary Fellow of the Royal College of Surgeons in 1900.

Early in his career Roddick came under the influence of Lister, and was one of the first surgeons in Canada to appreciate the true significance of the antiseptic system; to his precept and example the rapid adoption of the method by Canadian surgeons was largely due. Roddick entered the Canadian Parliament in 1896 as member for Montreal West, mainly with the idea of serving the profession and removing some of the legislative anomalies which then existed. When the British provinces became federated in 1867 under the

British North American Act the governance of educational matters was taken from the federal authorities and handed over to the provinces; accordingly, each established its own medical board or council, with power to grant a licence to practise, either after examination or simply on presenting the diploma of certain recognized universities. One result was that the holders of diplomas or degrees obtained in the British Isles could not legally practise in Canada without obtaining a licence from the provincial authority; correspondingly, Canadian graduates could not be registered here. The Medical Act passed by the British Parliament in 1896 to some extent removed the disability of Canadians in this country, for it permitted the registration of a person holding a recognized colonial medical diploma, but only if he was by law entitled to practise medicine, surgery, and midwifery in the Dominion of Canada. The Act, however, did not remove the Canadian disability for two reasons:

first, because there was no registering authority for the whole of Canada, and secondly because the Act required that before a Dominion practitioner could be registered here it must be shown that the Dominion afforded to registered medical practitioners of the United Kingdom such privileges of practising in the Dominion as established complete reciprocity. It was this situation that Roddick resolved to do his best to change. He travelled into every province of Canada in the course of his propaganda, and eventually (though after he had left the Canadian Parliament) the Canadian Medical Act was passed in 1912; he was elected first President of the Medical Council of Canada, established in accordance with its provisions. In this way he rendered immense service to the profession, and did something towards the consolidation of the British Empire—a cause always dear to his heart—by making the Canadian doctor at home in this country and the British doctor at home in Canada.

SIR THOMAS RODDICK.

Sir Thomas Roddick was twice married—first, in 1880, to Miss M. McKinnon, who died in 1890, and secondly, in 1906, to Miss Redpath, who survives him. He leaves no children, but two sisters, who helped him in dispensing the friendly hospitality he showed to members of the Association in 1897.

For the following tribute to Sir Thomas Roddick we are indebted to Dr. J. G. Adams, Vice-Chancellor of the University of Liverpool, who, as professor of pathology, was his colleague at McGill University:

For his personality and through what he accomplished for the profession Sir Thomas Roddick was deservedly looked up to as the leading figure in Canadian medicine of his generation. As is well shown in the obituary notice, he was the outstanding figure in the long-continued fight to obtain federal registration. The eventual victory owed everything to his persuasive pleading and personal popularity. Roddick, indeed, enjoyed his popularity. He loved to please people, and suffered at times from the very defect of his virtue in that he too easily promised to do those things which he could not perform; yet even those whom he disappointed in this way could not but fall victims to his geniality and inherent kindness. He was an admirable lecturer and a most popular Dean of the Medical Faculty at McGill. Of late years he had been keenly anxious about his own health and had gradually passed into retirement, so that it is difficult for the present generation to recognize the influence

he exerted during his full maturity from 1890 to 1910. That of which he was most proud was his early association with Lister and the part that he played in introducing the Listerian methods into Canadian surgery. Nor has his influence been confined to Canada. The national registration system which he established and its success has encouraged the leaders in the profession south of the line to move in a like direction. There has been the same problem in the various States as has existed between the Canadian provinces, so that a Massachusetts physician, for example, could not practise in the State of New York if he did not possess a New York licence. Only within the last few years there has been a successful movement to introduce legislation and the establishment of a recognized federal medical body whose examinations and diploma shall be accepted by all the States.

NORMAN DALTON, M.D.LOND., F.R.C.P.,

Consulting Physician to King's College Hospital; Fellow of King's College, London.

For some two years past the manifest signs of physical decline had told those who knew Dalton that the sands of life were running out for him apace, and the end came, in his 66th year, on Friday, March 9th, at his house in Hampstead. Born in Demerara in 1857, the youngest of a family of nine children, his father was chief postmaster of British Guiana. After some preliminary education at Queen's College, Demerara, he came to England at the age of 16 and joined Christ's College, Finchley. Two years later he passed on to the Medical School of King's College, where and at London University he won many honours. First qualified in 1879, he became M.B. in 1880, M.D. in 1882, and was elected a Fellow of the Royal College of Physicians in 1894. In 1886 he was appointed assistant physician at King's College Hospital, being already pathological registrar. In 1893 he was made professor of pathological anatomy, and at the time of his retirement from the staff only a few months ago he was senior physician and joint lecturer on medicine. He had been examiner in medicine both at London University and the Conjoint Board, and physician to two important life assurance companies—the National Provident Institution and the Scottish Union and National. During the war he gave assiduous service to the 4th London General Hospital and rose to the rank of lieutenant-colonel.

Only the would-be biographer knows how difficult it is to breathe again the breath of life into a dead man's self and give a fleeting resurrection to his personality. One is so apt to slip aside from the strait way of truth into the turgid eulogy of an apotheosis, or into a sterile catalogue of the material circumstances of his life, without regard to the spiritualities that make a study of the life profitable. Generations of King's men will think of Dalton first, in association with the post-mortem room; where he presided as pathological registrar for some twenty-five years; they will picture him clad in a long white mackintosh reaching from his chin to the soles of his feet, and advancing to his work with a very large knife in hand, which he carried much as a life-guardsmen carries his drawn sabre; he was a quick and neat worker, and his demonstration of the morbid conditions was precise, clear, and picturesque. His lectures on morbid anatomy gave students all they needed for examinations in simple direct language, that stuck in the memory, and he took pains to illustrate them by copious drawings and microscopic slides, all by his own hand. His long service in the post-mortem room led him to look at clinical questions too exclusively from the standpoint of morbid anatomy, and he took only a half-hearted interest in the great advances in the pathology of the living, in the departments of bacteriology, clinical pathology, and biochemistry that have been the outstanding feature of the three last decades. As a clinician he was a good teacher of the physical examination of patients, always correlating the signs to the structural changes they seemed to imply. Many signs to the structural changes they seemed to imply. Many King's men will remember with gratitude his teaching at a time, now happily long past, when in the aftermath of a galaxy of great clinicians the visiting staff did not lavish instruction on their students. For years he held a popular coaching class, the material of which formed the basis of a little book, *Aids to Medicine*, subsequently published by him. With Dalton conservatism was bred in the bone; the methods that had sufficed for the great clinicians he had served, notably Sir George Johnson, seemed to him to be sufficient for all time. Thus it came about that with the passing of morbid anatomy as the pivot of clinical medicine

Dalton came to be a man ploughing a lonely furrow; no visions of a promised land tempted him to explore the large *terra incognita* that lies beyond the confines of the dead-house.

Dalton was a very small man, and regarded this as a serious handicap to professional success: to think it so was to make it so, and to lay up unhappiness for a sensitive nature. Though a man of true courage, physical and moral, he would quail beneath the buffetings of fortune. It was not given to him to gather in profusion the rare and refreshing fruit of successful consulting practice. The courting of this coy and fickle goddess has left many another heart sick and sad. Perhaps he would have found a fairer field for his warmth of heart and faculty for unselfish service in the less exotic atmosphere of general practice.

Nowhere was Dalton so happy as among his patients at Drury Lane Dispensary, with which he had been connected for many years: there heart spoke to heart without restraint or artifice. They would confide in him their domestic concerns as well as their ailments, and to come away with a bunch of flowers or a bag of fruit given as a thank-offering by some poor woman was a real happiness to him.

There was a strong touch of Bohemianism in Dalton's make-up: no kipper was ever so tasty as those he used to toast before the fire in his early years in chambers at Clement's Inn. He was in his element at a men's card party shrouded in an impenetrable atmosphere of smoke, or seated in the ring at Lord's or the Oval, with no companions but his pipe and a newspaper, which served successively as seat, water-proof, plate, and mental pabulum according to the weather and progress of the play. He had read widely in both English and French literature; his taste directed him mainly to the earlier English fiction, but he had read much poetry as well. He read thoughtfully and formulated precise judgments on what he read; his attitude was rather critical than appreciative, for he was more apt to see the blemishes than the beauties, and to dwell on them.

Though a titular bachelor, Dalton was in full measure a family man; his home in the tropics had been broken up by the death of his father in Demerara while he was a boy of 17 only. Under his hospitable roof-tree in Mansfield Street the remnants of a scattered family found haven for many years; there also he became the devoted guardian of six children of a dead brother: the loss of one of these nephews in the late war hit him very hard. Dalton had many friends at his hospital, as two presentations on his recent retirement—the one from past and present nurses, the other from staff and students, commemorating his long and devoted service to the medical school—testified abundantly.

Circumstances, not natural temperament, for there was gaiety very close beneath the surface, made Dalton in later years a convinced pessimist. His friends grieved to see a cloud of despondency settle on him, as with advancing years he retired more and more into himself. It was hard to tempt him away from the solitude of his little garden in Hampstead: there at least he need not expose a warm heart to the chill of an uncongenial world. There he would watch the swelling of each bud and the unfolding of each flower with all the fondness of an expectant mother: the friendship of inanimate things became his all in all; he still had affection to lavish and he lavished it on them. Among his flowers his thoughts would often turn back to his boyhood in the tropics, to its simple freedom, to the sunlight, the warmth, and the lush vegetation, to the sensuous charm of all that he had exchanged for the pomp and gloom of the great heartless city to which destiny had chained him. May his Spirit bask in eternal sunshine in a garden of the flowers that he loved so well! The burial was in Hampstead Cemetery on Tuesday, March 13th, and a memorial service was held at St. Clement Dane's Church.

Dr. WILLIAM MACDERMOTT, who died on January 31st, was a son of a very highly esteemed minister in Belfast. He studied in the Queen's University of Belfast, took the degrees of M.B. and B.Ch. in 1914, acted as house-surgeon and as house-physician in the Royal Victoria Hospital, Belfast; he then joined the R.A.M.C. and served as temporary captain for the rest of the war. After demobilization he settled in England, but a low form of pneumonia set in and he had to return to his home, Wakefield, heed the unavailing care and attention of his friends. He died on February 29th, 1923, at the age of 59. His family is felt with his family in the great war.

Dr. HUGH KNYVETT, who died at Sidmouth on January 27th, in his 79th year, was the son of a Yorkshire vicar, and early in life emigrated to New Zealand. He remained there for twenty-four years, rising from a shepherd to manager of a sheep station. At the age of 40 he returned to England and entered Guy's Hospital medical school as a student; he took the Scottish triple qualification in 1889. Subsequently he practised at Butleigh for many years, and was well known also in Taunton, where he served on the National Service Medical Board. Five years ago he went to live at Sidmouth, last spring taking a trip to New Zealand and back as a ship surgeon. Dr. Knyvett had a charming personality and was an excellent all-round sportsman.

Dr. DAVID CARNEGIE ALEXANDER, M.C., late Captain R.A.M.C. (T.C.), died in Florida on February 17th. He was the eldest son of the late Charles Alexander, of Upland, Selkirk, and was educated at Edinburgh, where he graduated M.B. and Ch.B. in 1905. He took a temporary commission as lieutenant in the R.A.M.C. on February 15th, and was promoted to captain after a year's service. He was gazetted to the Military Cross on November 4th, 1915, being one of the earliest to gain that distinction.

## Medical News.

Dr. LEONARD HILL, F.R.S., director of the department of applied physiology and hygiene at the Medical Research Institute, Hampstead, has been presented by the Council of the Royal Institution of Mining and Metallurgy with the "Consolidated Gold Fields of South Africa, Ltd." Gold Medal in recognition of his valuable researches on ventilation and his paper on ventilation and human efficiency, contributed to the *Transactions*.

SIR HUMPHRY ROLLESTON, K.C.B., M.D., has been appointed chairman of the Central Joint Voluntary Aid Detachment Council, which is composed of representatives of the War Office, the Territorial Army Associations, the Order of St. John of Jerusalem, and the British Red Cross Society.

Mr. H. W. CARSON, F.R.C.S., will give the Hunterian Oration to the society of that name on Monday next at 8.30 p.m., at the Mansion House, London. The subject is the evolution of the modern view on septic peritonitis and its applications.

Dr. A. A. MATHESON of Edinburgh was recently presented with a silver tea service at a reception given in his honour by a section of the Jewish community in Edinburgh. Rabbi Dr. Salis Daiches, who made the presentation, thanked Dr. Matheson for the services he had rendered to his Jewish patients, and at the same time presented Mrs. Matheson with a fitted dressing case.

The forty-fifth festival banquet of the Irish Medical Schools' and Graduates' Association will take place this day (Saturday, March 17th—St. Patrick's Day) at Paganini's Restaurant, after the annual meeting, when Dr. J. A. Macdonald will resign the presidential chair to Sir William Taylor, K.B.E., C.B. Tickets for the dinner, 9s. each, may be obtained by any Irish graduate from the honorary secretary, Dr. Meyrick, 48, Ennismore Gardens, S.W.7.

A MEETING of the Fellows of the Royal Society of Medicine was held on Tuesday evening, when a paper was read by Mr. J. E. Adams on the urgent need for education in the control of cancer. Mr. C. P. Childe, Lord Dawson of Penn, Mr. W. G. Spencer, the Hon. Sir Arthur Stanley, Sir Napier Burnett, and others, addressed the meeting, and resolutions were unanimously carried urging that the public should be given more information as to the early signs of cancer, and requesting the British Red Cross Society to conduct a publicity campaign by means of lectures and pamphlets, and the Council of the Royal Society of Medicine to nominate a standing committee to supply information to the Red Cross Society suitable for public dissemination. A report of the proceedings will appear in our next issue.

Mr. T. H. KELLOCK, surgeon to the Middlesex Hospital and consulting surgeon to the Children's Hospital, Great Ormond Street, who died last December, disposed in his will of net personality amounting to £52,760. He bequeathed £500 to the Hospital for Sick Children, to be expended on some specific object which shall not increase the annual expenditure of the hospital; £100 as a permanent endowment of the medal for the nurses' prize instituted by him; and £100 each to the Santa Claus Convalescent Home for Children at Highgate, the Invalid Children's Aid Association, and the

National Society for the Prevention of Cruelty to Children. He bequeathed also personal legacies to certain nurses and others who had worked at the two hospitals with which he was connected.

NEW rules, framed in accordance with the recommendations of the Committee of Inquiry on Artificial Limbs, have been issued with the approval of the Minister of Health, for the guidance of medical superintendents of limb-fitting centres responsible for the ordering of artificial limbs for pensioners. The artificial limb ordinarily supplied will be one of the Ministry's standard pattern legs of wood and leather, but where it is considered that a peg leg will be more suitable for the avocation of a pensioner such a leg may be ordered as one of his two artificial legs. Metal limbs may be supplied for cases of amputation above the knee at the discretion of the surgeon. Metal limbs for amputations below the knee will be supplied only when in the surgeon's opinion special surgical or medical conditions render a wooden limb unsuitable.

THE annual debate of the Chelsea Clinical Society will be held in the Club Room of St. George's Hospital Medical School, S.W., on Tuesday, March 20th, at 8.15 p.m. The subject selected for the debate is Visceroptosis; it will be opened by Sir Charlton Briscoe, followed by Dr. Robert Hutchison, Mr. Ivor Back, and Mr. Mortimer Woolf.

A PETITION for the granting of a charter of incorporation has been presented to His Majesty in Council on behalf of the Wolverhampton and Staffordshire General Hospital.

WE are asked to state that hospitals in the County of London or within nine miles of Charing Cross desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1923 must make application before March 31st to the Honorary Secretaries of the Fund, 7, Walbrook, E.C.4. Applications will also be considered from convalescent homes, which are situated within the above boundaries, or which, being situated outside, take a large proportion of patients from London.

AT a social meeting of the Royal Society of Medicine on the evening of March 21st Dr. H. C. Cameron will deliver a short address at 9 p.m. on the mystery of Lord Byron's lameness.

MESSRS. JOHN BANTHOLMEW and SON of Edinburgh have issued a railway map of the British Isles, showing the new groups by means of different colours. The L.M.S. (London, Midland and Scottish) seems to be nearly ubiquitous, extending from London to Thurso and from Yarmouth to Swansea. The colours chosen are distinctive and the map, it is hardly necessary to say, is very well produced.

THE thirty-fifth German medical congress will be held next month in Vienna under the presidency of Professor K. F. Wenckebach. On the first day (April 9th) a discussion on encephalitis lethargica will be opened by von Economo of Vienna and Nonne of Hamburg. In the afternoon of the following day there will be a demonstration of patients suffering from disorders of internal secretions. On April 11th a discussion on arterial high pressure will be opened by Durig of Vienna and Volhard. Papers will be read on each of these days, and also on April 12th. On Saturday, April 14th, there will be demonstrations in the morning and excursions in the afternoon.

THE National Association for the Prevention of Tuberculosis will hold its ninth annual conference in Birmingham on the invitation of the Lord Mayor of that city. The conference will open on Thursday, July 12th, and close on the afternoon of the following day. The chief subjects for discussion are: The care of advanced cases of tuberculosis, especially as regards prevention of infection; the extent and nature of damage done by tuberculosis derived from infected milk; the relative prevalence of tuberculosis among workers in different trades; and the amendments which should be made in the procedure for the notification of tuberculosis. Opportunities will be afforded for persons attending the conference to visit various institutions concerned with the prevention and treatment of tuberculosis.

A MEETING of the Association of Economic Biologists will be held at the Imperial College of Science on Friday next, March 23rd, at 2.30 p.m., when Professor J. H. Priestley of Leeds will read a paper on the causal anatomy of potato tuber, and Mr. E. R. Richards will discuss the control of cellulose decomposition and its applications.

MESSRS. A. E. DEAN and Co. (Leigh Place, Brooke Street, Holborn, London, E.C.1) have issued a list of their diathermic apparatus, with explanatory notes.

PERU is free from yellow fever for the first time in its history. According to Dr. Hanson, Director of Public Health of the Republic, this is a result of the yellow fever campaign carried out by the Rockefeller Foundation and the Peru Government; no cases have been reported since August, 1921.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attology, Westrand, London*; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Medisecra, Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### WHITE ANTS.

A CORRESPONDENT in West Africa asks for advice as to the destruction of white ants. His woodwork, books, and clothes are, he says, destroyed by them, and he has found tar, kerosene, cyllin, mercury perchloride, and solution of chlorine of no avail. Even if expelled for a time they return within twenty-four hours.

\*\* We have made some inquiries, and learn from Sir Arthur Shipley that it would be desirable to ascertain the species of termites. Dr. Guy Marshall, C.M.G., F.R.S., of the Natural History Museum, has been good enough to send the following general observations:

I fear the matter is not so simple as it might seem, for it is hardly possible to make useful suggestions without knowing how the house is constructed. If, as is often the case in the tropics, the house is built on piles or piers of brick, something might be done; if, however, it has been built flush on the ground, without foundations, the chances of finding a satisfactory remedy are very remote. Further, it is necessary to know the materials of which the walls are made and the nature of the flooring. In houses built of unprotected timber or sun-dried bricks, the case is practically hopeless once the walls are infested by the termites. The only real protection lies in proper construction. On the second course of bricks above the foundations sheet zinc should be laid throughout so as to project two or three inches clear on both sides; then at least two courses of bricks should be built on top of this before the floor joists are laid. Where houses are built on piers there should be a sheet of zinc right through the middle of each pier and projecting at least two inches clear all round. Otherwise the only thing to be done is to search for the nests under the floor and immediately round the house and treat them with a heavy poisonous gas, such as carbon bisulphide. But this is a tiresome and costly business, and will probably have to be repeated at intervals. When the floor and walls are infested the only course is to keep one's belongings on wooden stands away from the walls, the legs of the stands being placed in saucers or tins. If the latter are filled with paraffin or occasionally dusted with Keating's powder they also serve to keep away house ants, which are often a serious nuisance in the tropics.

#### BUTYN.

DR. M. D. THAKORE (Doncaster) writes to point out that the cost of butyn recommended recently by Mr. Beaumont as a local anaesthetic (January 13th, p. 57) militates against its general use. He recently had to pay 12s. 6d. for 1 oz. of 2 per cent. solution.

\*\* We are informed by Dr. Harrison Martindale that the cost of butyn, which is made in America, is exceedingly high, but that the price seems at present justified. The price to medical men is 7s. 6d. a gram, so that an ounce of 2 per cent. solution should cost 7s. or 8s.

#### INCOME TAX.

"R. I. I." noted in 1920-21 as a non-resident house-surgeon, and deducted £3 3s. a week from the amount received as representing the cost of rooms and attendance.

\*\* Apparently the deduction cannot legally be made. Our correspondent is assessable on the gross amount less expenses incurred wholly and exclusively and necessarily in the performance of the duties of his office; personal expenses of the kind mentioned do not fall within that category. The point underlying the inquiry is that a resident house-surgeon receiving

board and lodging in kind is in the unusually favourable position of not being liable to tax on the value thereof—but that is not the case here.

"NEBO" has a daughter over 18 years of age whom he maintains at a cost of £140 per annum in an asylum.

\*\* The only allowance that can be claimed is the statutory allowance of £25. The Guide to which "Nebo" refers was written by Mr. P. Sulley and is published by Thos. Nelson and Sons, Ltd., Edinburgh. That address is sufficient, though doubtless any local bookseller could obtain the book.

### LETTERS, NOTES, ETC.

#### THE PREVENTION OF SEPSIS AFTER BLADDER AND PROSTATE OPERATIONS.

DR. A. LAPHORN SMITH (London, W.), who expresses the interest and pleasure with which he read Sir John Thomson-Walker's address on problems of prostatectomy (BRITISH MEDICAL JOURNAL, January 27th, p. 133), writes in praise of hexamine. From his experience of transplantation of the ureter and the repair of many vesico-vaginal fistulae, he feels confident that primary union would not have been obtained without the hexamine and drainage. "I have always given hexamine," he continues, "both before and for several weeks after my plastic operation on the bladder and ureters. As all my patients were women I had no difficulty in leaving a self-retaining glass catheter in the bladder for one or two weeks, with a thin, light rubber tube attached leading to a receptacle under the bed. This gives the bladder absolute rest. The perforated glass bulb of the catheter is only half an inch from the entrance of the two ureters, so that the urine never touches the bladder wall at all."

#### PSYCHOLOGY AND MEDICINE.

DR. RICHARD GILLBARD (Willesden Green), writing with reference to Sir Frederick Mott's lecture (March 10th, p. 403) on psychology and medicine, recalls a passage in a lecture in which the late Sir George Savage combined two famous sayings: "When I see a precocious child I say to myself, there, perhaps, goes a Shelley; there, perhaps, goes insanity. The line of demarcation between insanity and genius is a faint one."

#### CRAVING FOR TOBACCO.

LIEUT.-COLONEL G. HARRISON YOUNGE, F.R.C.S.I., R.A.M.C. (ret.), writes: Cases are occasionally seen where it is desirable, or even urgently necessary, to discontinue smoking and it is more than probable that instances of this kind will become much more common in future owing to the great increase of smoking amongst women, whose nervous and circulatory systems are so susceptible to the injurious effects of tobacco. Many years ago I found it necessary to stop smoking owing to chronic pharyngitis and I shall never forget the long weeks of intense misery which were endured until the craving for tobacco eventually subsided. Quite recently I have discovered a way in which smoking may be stopped without difficulty and without suffering of any kind. More than a year ago, owing to a return of chronic pharyngitis, I decided to try a herbal smoking mixture. Smoked from an ordinary briarwood pipe in the usual way, it completely satisfied the desire for tobacco and its use was quickly followed by a decided improvement in the symptoms of catarrh and irritation of the throat. After some months of its use I found that the desire for tobacco had completely disappeared and that it was possible to stop suddenly the herbal smoking mixture without difficulty or inconvenience of any kind. If occasionally the thought occurred, "A pipe would be a pleasure," it was only necessary to suck a peppermint lozenge to remove completely this scarcely desirable prompting.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 36, 37, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 67.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

## An Address ON TUBERCULIN IN THE DIAGNOSIS AND TREATMENT OF TUBERCULOSIS.\*

BY  
SIR ROBERT PHILIP, M.D., LL.D., F.R.S.E.,  
PROFESSOR OF TUBERCULOSIS AND EXAMINER IN MEDICINE,  
UNIVERSITY OF EDINBURGH.

IN current statement as to the significance of tuberculin in relation to tuberculosis—and still more as to its practical application—one is frequently up against a looseness of conception regarding essential facts. These facts form the basis of any sound practical application of tuberculin in diagnosis or treatment. While the facts are in chief part definitely determined, there has been little attempt to correlate them as the basis of practical procedure.

My aim is to recall fundamental positions and try to show how these afford points of departure for practical observations regarding tuberculosis, with a view to the final goal of *detubercularization*. This will include considerations bearing on both diagnosis and treatment. In particular I shall take the opportunity of urging once more the therapeutic value of the *percutaneous* exhibition of tuberculin as recommended by me for many years.

While the percutaneous method is serviceable in the treatment of tuberculosis generally, it has a special range of application in the earlier manifestations. It exerts a remarkable inhibitory influence on the first buddings of tuberculosis in childhood. Continued observation as to its effects throughout long periods in many types of tuberculosis has led me to conclude that the method, consistently applied, is capable of effecting the nearest approach to *detubercularization* yet realized.

### *Experimental Tuberculosis.*

The first postulate is a clear conception of tuberculosis, or, stated otherwise, of the process and effects of tubercularization. When an animal, say a guinea-pig, is inoculated with a sufficient dose of tubercle bacilli, whether by injection into the tissues or by inhalation, the animal becomes tubercularized. In illustration, take the effects following the subcutaneous introduction of bacilli—for example, into the groin. Within ten days or thereabout, a local sore is produced at the point of puncture, which tends to continue in indolent fashion throughout the life of the animal. Following the appearance of the sore, more distant effects are speedily registered—first in lymphatic glands nearest to the sore, and then successively in glands and groups of glands at increasing distance from the initial lesion. Ultimately the lymphatic system tends to be involved universally. At varying dates the several viscera—spleen, liver, lungs, kidney—become implicated. The order of events is subject to variation, according as the position of primary inoculation is varied. The histological changes are essentially similar throughout the process. These manifestations in glands and viscera, however variable in degree, constitute collectively the *local effects* of tubercularization.

In addition to these, and dependent on the gradual extension throughout glands and viscera, may be registered more general changes—conveniently termed *systemic effects*. While at first the inoculated animal may present little evidence of disturbance, maintaining and perhaps even increasing in weight, physiological disturbance may be observed sooner or later. The animal tends to assume a shabby aspect, natural firmness is replaced by hypotonus, weight is dropped, the quality of the coat deteriorates, and spontaneous motility slackens. An advancing marasmus leads towards death. Such disturbance forms collectively the *systemic effects* of tubercularization.

### *Complete Diagnosis.*

What occurs in the inoculated animal—guinea-pig, rabbit, or other—may be traced in the tubercularized human subject, with variations, according to the point of primary inoculation, the dose of infection, and the resistance offered, influenced as the last may be by initial qualities in the individual and by varying conditions of environment. In concluding a diagnosis in the human subject it is of the first importance that observation should be directed explicitly and fully to both groups of phenomena.

\* Delivered at the Tuberculosis Society of Scotland.

*Local (focal)* effects in viscera and other structures must be carefully searched for throughout the body. We must get away from undue concentration on one or other focal manifestation, wherever that may happen to be. It goes without saying that a local effect may be such as to call for immediate local treatment, whether in gland, lung, kidney, or elsewhere. But the adoption of such local measures must not be allowed to obscure the presence of tuberculosis in other organs and tissues. The diagnosis of local disorder must be as complete as possible. Beyond the local disturbance, a careful estimate must be made of the degree of general physiological disturbance—in other words, of the *systemic* effects of tubercularization, as these may be registered by evidence of neuro-muscular intoxication (langnor, feeling of tiredness, muscular dystrophy, vasomotor phenomena, etc.), by temperature variation, circulatory failure, etc.

The diagnosis, then, of tuberculosis in a given case should be much more complete and definite than it generally is. The determination that the tubercle bacillus is the cause of symptoms occurring in relation to lung, kidney, or other organ—whether that determination be based on actual discovery of the tubercle bacillus in discharge or excretion or on other grounds—is merely the first step to the completer diagnosis which is essential in every instance. The complete diagnosis must be based on the fullest examination possible and be given in terms both of local and of systemic effects.

### *Tuberculin in Diagnosis.*

Tuberculin—using that term in wide sense to include the considerable variety of extracts obtainable by various processes from a culture of the tubercle bacillus—may be said to possess, by reason of its origin and its effect on tubercularized individuals, specific relationship to tuberculosis.

The animal inoculated with tubercle bacilli and the tuberculous patient respond in remarkable fashion to tuberculin. While the individual who remains free of tuberculous infection can tolerate large doses without production of symptoms, the individual who is tubercularized, even in slight degree, yields a response both local (focal) and systemic. The nicety of diagnosis by means of tuberculin depends on the exactness with which the response, focal and systemic, is appraised.

The *focal* effects consequent on a test injection of tuberculin are most directly illustrated by the changes observable in a superficial patch of lupus. These include congestion with increased redness and swelling of the patch itself and the neighbouring tissue, with subsequent exudation and, it may be, crust formation, the effects lasting for several days. The focal effects which are so evident on the surface in the case of lupus are reproduced in similar fashion—it may be in aggravated degree—in relation to tuberculous foci wherever situated in the body. They are to be carefully sought for by all the available methods of physical examination.

In addition to the focal results, *systemic* effects from tuberculin may be traced in the occurrence of malaise and probably disturbance of temperature and circulation. The systemic effects, which may be slight in a case of limited lupus, are correspondingly greater according as the area involved is larger. They become pronounced, and may even be serious, where the foci of tuberculosis are extensive or numerous, more especially in the case of visceral involvement.

### *Rationale of Tuberculin as a Therapeutic Agent.*

In the employment of tuberculin for therapeutic purposes the twofold aspect of tuberculosis must be kept steadily in view. For effective cure both focal and systemic effects of tuberculin are serviceable. If tuberculosis is to be cured locally, wherever the focus be situated, there must be a hastening of the natural tendency towards cicatrization. Such cicatrization is the basis of permanent arrest of the tuberculous process, whatever be the tissue immediately involved. The local stimulation by tuberculin at each tuberculous focus is an important step towards that end. The remarkable effects in this direction are conveniently studied from week to week in connexion with a superficially placed tuberculous lesion under treatment by tuberculin. In the current discussion of tuberculin therapy too little attention seems to have been directed towards this aspect of the subject.

The systemic intoxication occurring in tuberculosis is countered, through the antigenic properties of tuberculin, by the elaboration within the affected system of antibodies or the enrichment of these, if they are to be conceived as already existing.

*Choice of Tuberculin.*

The group of fluids collectively termed tuberculins is not very well defined. Remarkable differences of opinion have emerged as to the relative value of different tuberculins. Amidst such diversity it is difficult either to arbitrate or reconcile.

Broadly stated, the conclusion I have formed, after prolonged observation in different directions, is that a tuberculin is likely to be serviceable in proportion to the closeness of its relationship to the tubercle bacillus and the directness of its mode of production. It has seemed to me that the simpler the constitution of the culture medium on which the tubercle bacillus is grown, the more likely will the first of these conditions be fulfilled. On that account the tuberculin of Béraneck has been advocated by me for therapeutic purposes—obtained as it is by a simple process of extraction from a growth of tubercle in a medium free from the addition of artificial peptones.

Whatever be the tuberculin employed, the rationale of its activity in both diagnosis and treatment seems to be that when introduced into the body it acts as an antigen. Tuberculin reactions are based on the interreaction of antigen and antibody in presence of complement.

Since the first introduction of tuberculin in 1890 I have used a considerable variety of products. The net result of those observations has been to reinforce the conclusion based on more theoretic considerations. The tuberculins I use most commonly—both for diagnosis and for treatment (the latter especially in ways to be detailed presently)—are Koch's original tuberculin and Béraneck's tuberculin, in varying excipient and dilution, according to the nature of the case and the purpose in view.

*METHOD OF EMPLOYMENT IN DIAGNOSIS.*

The familiar division into *subcutaneous*, *cutaneous*, and *percutaneous* methods recalls sufficiently the chief points.

*(a) Subcutaneous.*

As was natural, Koch's early proposals were on the line of subcutaneous injection, and attention was drawn to effects following such introduction into the tuberculized subject. These results were suitably grouped as (1) *general*—for example, temperature and pulse disturbance; (2) *focal*—that is, changes occurring in the tuberculized area such as I have already described in relation to lupus; and (3) *local*—that is, changes occurring more or less definitely about the point of puncture.

*(b) Cutaneous and Percutaneous.*

The last-named results—that is, local results—are conspicuous in proportion as the tuberculin in course of introduction comes into contact with the skin structures. Such evident local phenomena naturally became the object of closer observation on the part of numerous workers. Thus emerged the surface reaction associated with the name of von Pirquet, and that associated with the name of Moro.

It is needless to go into details of procedure in respect of these surface tests or the interpretation of results thereby obtained. It is sufficient to recall the fact that the wide application of such methods, which speedily followed von Pirquet's pronouncement, resulted in a fresh orientation of the tuberculous problem—in respect more especially of the frequency of infection and its incidence in childhood.

The observations based on the von Pirquet and allied procedure have proved of epidemiological rather than immediate clinical value. They have revealed that tuberculosis is almost universally distributed throughout civilized communities and that the occurrence of infection takes place for the most part during childhood. A positive reaction to the von Pirquet or to the Moro test indicates that the patient is tuberculized. So long as the reaction remains positive the patient cannot be said to be detuberculized in the strict sense, whatever course of treatment may have been followed.

This negative fact has its reassuring aspect in light of the "phenomenon of Koch." The tuberculized animal is not infected afresh by the introduction of living tubercle bacilli. The results following attempts to reinoculate an already tuberculized animal differ widely from those following the primary inoculation and are comparable with the results following a considerable dose of tuberculin when administered to the tuberculous subject.

The further life history of the tuberculized individual is dependent on the degree of his resistance. This varies from time to time by reason of varying physiological conditions

of the individual himself and variations in the conditions of his environment.

*Interpretation of Response.*

While the local manifestations following the diagnostic test may reveal little beyond the fact that the subject of the test is tuberculized, the systemic, and, in still greater degree, the focal effects are much more definite and detailed. When carefully scrutinized and analysed they are capable of affording exact information—both qualitative and quantitative—as to the presence and distribution of the disease.

A correct interpretation of the evidence thus attainable is dependent on the experience of the observer and the delicacy of the methods employed. When properly carried out, the procedure affords a demonstration regarding the extent and character of the existing tuberculous involvement which is remarkably precise. Few diagnostic procedures in clinical medicine possess greater nicety in respect of the information thereby obtained. Of attendant risks frequently cited by critics of tuberculin I have seen none, when the tests have been competently carried out. The postulate of competence in this case is no less necessary than in the case of many other exact clinical methods.

*METHODS OF EMPLOYMENT IN TREATMENT.**(a) Subcutaneous.*

The therapeutic application of tuberculin has for the most part been carried out by means of subcutaneous injection. The value of the procedure has been assessed variously by different writers. From the statements made in current literature one fact seems to emerge clearly—namely, that the judgements expressed are frequently second-hand, not based on serious observations of the writer himself. Sometimes, even if based on the writer's experience, negative statements are less convincing than they might be by reason of apparent haste and insufficiency in the procedure that has been followed.

The competing claims of different schools of thought as to the rationale of the action of tuberculin have led to confusion and embarrassment. Exaggerated claims for one or other scheme of dosage have been the fruitful cause of not unnatural scepticism on the part of the practical man who, in rule of thumb fashion, may have tried one or other system and found it wanting.

The continuous use—since its introduction—of tuberculin in suitable cases has convinced me that the procedure has specific curative value. The case must be properly selected—in other words, the remedy must be exhibited at the appropriate stage—and the dose must be suitably graduated according to the result obtained from time to time in the given case. These are details which demand judgement based on experience. The interval between successive doses must be similarly gauged, as also the duration of treatment and the desirability, after appropriate resting period, of a further series of injections. Some cases lend themselves to less intense, others to more intense, lines of treatment. A satisfactory result cannot be looked for unless efficient treatment be maintained for a sufficient length of time. Throughout the whole period of treatment watchful care will be taken to detect the slightest expression of super- (hyper-) susceptibility. If this supervene, dosage should commonly be reduced or the exhibition of tuberculin suspended for the time being.

*Technique.*—The selected tuberculin is suitably diluted with normal saline, with the addition of 1/2 per cent. phenol in the case of weaker solutions for purposes of conservation. With simple aseptic precautions, the injection is conveniently made into the areolar tissue beneath the skin of the back. Care should be taken that the point of the needle pierces the skin completely. In this way the occurrence of local irritation and swelling (phlegmon) about the point of puncture is avoided.

*(b) Cutaneous and Percutaneous.*

Observation of the effects produced locally in relation to the skin have led to the exhibition of tuberculin cutaneously and percutaneously.

*Cutaneous (Sahli's Method).*—Thus Sahli was led to substitute for subcutaneous injections a process of multiple cutaneous vaccinations by means of a special needle. More recently he has introduced the practice of intradermic injection, the tuberculin being deliberately introduced into the skin tissue. He has shown that a considerable part of the tuberculin thus injected is absorbed and produces general effects. He believes that the intensity of the intradermic

reaction affords a gauge of the degree of immunity of the patient—that is to say, of his susceptibility to tuberculin—and is at the same time a guide to the determination of the appropriate dose, and so to the avoidance of troublesome reactions, systemic or focal. Treatment is thus directed from time to time by effects open to the eye of the physician. The evidence submitted by that distinguished observer in favour of the therapeutic value of tuberculin and of the efficacy of this method of introduction is convincing.

*Percutaneous (Author's Method).*—For some twelve years I have been making extensive observations on the effects of the exhibition of tuberculin by percutaneous as opposed to subcutaneous method. These observations have led to very interesting results in a number of directions. For the present I limit myself to a brief statement regarding a therapeutic method which the experience of these years has remarkably justified.

One of the first points to emerge in the course of these studies was that, when tuberculin in varying combinations was rubbed firmly into the skin of a tuberculous patient, it was freely absorbed. More observed that a local skin eruption followed the inunction of tuberculin mixed with lanolin, and recommended the procedure for diagnostic purposes. Petruschky has testified to the absorption through the unbroken skin of tuberculin exhibited in the form of a liniment which he used in treatment.

Observations on a great variety of subjects satisfied me that the obvious local eruption was in many cases associated with signs of focal reaction, and in much slighter degree with evidence of general reaction. The focal changes may be readily followed in cases of lupus and other superficial manifestations of tuberculosis, as also in glandular tuberculosis. It is likewise traceable in pulmonary and other visceral tuberculosis.

#### Results and Advantages of Percutaneous Method.

My therapeutic procedure is based on these facts. Tuberculin administered percutaneously by inunction is absorbed and exerts a specific influence on tuberculous processes wherever situated, analogous to those resulting from subcutaneous injection. The curative influence becomes speedily obvious. I have records of its successful use in a great variety of tuberculous manifestations.

Assuming its therapeutic value, the method has numerous advantages over the other methods of exhibition. Something may be said for the absence of pain or discomfort. The procedure is not an operation in the mind of the patient. This has significance in all cases, but especially in children—the dread of the recurring puncture is excluded. The local (skin) reaction, while generally definite enough, causes little if any discomfort. The cutaneous response seems to afford in some degree a gauge of the susceptibility of the patient. In this way dosage may be regulated in respect of amount and frequency.

In simpler cases, with a few definite instructions from the physician, the method may be carried out to some extent by an intelligent nurse or parent, or, it may be, by the patient himself. In pulmonary and other visceral tuberculosis, greater caution is, of course, necessary, and procedure, dosage, etc., will be guided by observation of focal and systemic effects, in addition to those occurring on the skin surface. This necessitates careful surveillance on the part of the medical attendant.

The curative influence on superficial tuberculous foci (cutaneous, glandular, etc.) is commonly apparent within a few weeks and is as a rule continuous. Thus, for example, a crude agglomeration of enlarged glands becomes progressively reduced in size, the indefinite mass is resolved into individual discrete glands, each of which tends to get smaller and smaller until finally reduced to a mere fibrous remnant. These slowly remains may be felt for a long time. The process of recovery by cicatrization may similarly be followed in scrofuloderma and lupus. In the latter the advance of the curative process is, as might be expected, relatively slow. A similar retrogressive influence may commonly be traced in visceral tuberculosis.

#### Anticipative Detuberculization.

I have alluded to the advantage which the percutaneous method has in the case of children in respect of ease of administration. Its continued use in children leads to much more significant results. When the treatment (instituted, it may be, for an enlarged gland) is maintained for months—that is, long after the gland for which it was begun seems to

have recovered—there may be frequently traced evidence of a more general influence on enlarged lymphatic glands throughout the body, associated with a general improvement of health and condition, which is justly interpreted as an expression of progressive detuberculization. Our records include many children in whom such detuberculization has been effectually achieved. The remarkable progress from week to week compels attention.

I strongly advise the adoption of this line of treatment on the earliest indication of chronic glandular enlargement in children. In this way the process of tuberculization—so frequent in children—may be successfully countered at a time when the advancing infection is limited to the lymphatic system. By an arrest at that stage the graver incidents due to involvement of viscera are anticipated and prevented. Such a curative and preventive course of treatment may be suitably maintained for months without any disturbance of the child's ordinary life. The exhibition of tuberculin by inunction has the advantage that in most cases it interferes little with the life and occupation of the patient.

#### Formulae for Percutaneous Administration.

In developing the percutaneous method I have made very prolonged observations with various tuberculins in varying excipients. On the whole I am inclined to recommend the use of either Koch's original tuberculin or Béraneck's tuberculin. Both commonly effect a satisfactory surface response. Either tuberculin is used in varying strength from 10 per cent. up to 50 per cent. As excipient I prefer "eucerin"—that is, a mixture of 5 parts of oxycholesterine from wool fat and 95 parts of paraffin ointment. Eucalyptol in small quantities may be added for conservation of the ointment as in the following formula:

R. Tuberculin (Orig. K.) ...	...	...	10-50 per cent.
Eucalyptol ...	...	...	5 per cent.
Eucerin ...	...	...	ad 100.

Misce bene.

Sig.: Tuberculin ointment, with caution.

For simple cases treatment may conveniently be begun with 25 per cent. tuberculin. In young subjects, or where there is doubt as to the number and extent of foci involved, it is well to commence with 10 per cent. When the response to the lower dosage is slight, the proportion of the tuberculin is increased. In all cases attention must be paid not only to the local response but also to the focal and systemic effects.

The actual amount of tuberculin applied to the skin in a straightforward case (using, say, 25 per cent. dilution) may be estimated as approximately 0.1 c.cm. The ointment containing this is rubbed (worked) into the cleansed skin over an area of 1 to 2 square inches by means of a small sterilized glass rod. As already indicated, the inunction may be suitably repeated—in the absence of contraindication—once weekly. Where the response is slight the applications may be made at shorter intervals.

#### CONCLUSION.

It is an essential postulate for effective approach to the treatment of tuberculosis that we have in view the significance and potential of tuberculous infection in the life history of the infected individual. The possible resultants from infection are extremely various both in kind and in degree. Granted that a child has become infected, the variety of expression of such tuberculization is illimitable; from slighter manifestations hardly registrable, to one or other of the graver forms which may lead to crippling or death—and this at any point throughout life, short or long as that may be.

In order to meet the width and gravity of the issue, the aim of therapeutic procedure must be radical—that is, directed, not, as unfortunately much of the interference presently countenanced is, towards a mere incident of the disease, but towards the ultimate, essential cause of the spreading infection.

If the validity of any method of detuberculization be established it is clear that the earlier in the life history of the infected individual it is adopted, the speedier and completer will be the effect achieved. It is because extensive observations on a great variety of clinical conditions and at different ages have convinced me that the method proposed has effective value, not only in limitation of local effects but in the direction of general detuberculization, that I solicit for it your consideration and a patient trial. "Lightning" results are precluded by the nature of the process. It behoves us to remember that if it takes long to come, tuberculosis, at the best, takes long to go.

## An Address

ON

## CARDIAC PROBLEMS IN ADOLESCENT LIFE.

DELIVERED TO THE BUCKINGHAMSHIRE DIVISION OF THE  
BRITISH MEDICAL ASSOCIATION

BY

G. A. SUTHERLAND, M.D., F.R.C.P.,

PHYSICIAN TO THE PADDINGTON GREEN CHILDREN'S HOSPITAL;  
CONSULTING PHYSICIAN, HAMPSHIRE GENERAL HOSPITAL.

The problems in connexion with disease and disturbance of the heart vary to some extent with the period of life. During childhood and youth we find the foundation laid of organic heart disease, which in many cases causes no inconvenience to the patient until later on in life. On the other hand, the disease may have been so severe in childhood, especially in cases untreated, that the whole adolescent life is seriously crippled. Advancing years bring their degenerative changes, cardiac and vascular, of which not a trace is present in early life. Acute illnesses in the young are not accompanied by those serious cardiac complications which so often lead to cardiac failure in later life. The problems which I bring before you to-day are largely the ones which have confronted me in my ordinary work and which I had to try first to understand and then to solve. You will find that the ordinary textbooks rather leave you in the air as regards these problems because it is not their function to deal with the actual experiences of medical life and work. I propose, then, to give some hints as to how to approach these problems of cardiac disturbance and cardiac disease, so as to enable you to deal with the prognosis and treatment of the individual cases you are called on to deal with in practice.

## 1. CONGENITAL HEART DISEASE.

I do not refer here to cases which have been recognized early and watched through infancy and childhood, but to the unexpected discovery of a cardiac lesion, usually through the presence of a cardiac murmur. The boy or girl may be quite well and happy, the parents may have had no cause to suspect hidden trouble, but the doctor is often pained and puzzled and anxious as to what he ought to do. The murmur is often loud—in fact some of the loudest murmurs are found in connexion with congenital lesions. It is usually systolic in time, loudest at the base of the heart or at the left side of the sternum, and often quite audible in the back. On a systolic murmur alone it is not wise to make a diagnosis of the exact lesion—nor is it necessary. If a double murmur is heard at the base, running through systole and diastole—the so-called mill-wheel murmur—one can with confidence diagnose a patent ductus arteriosus. This is sometimes taken to be the double murmur of aortic disease—obstruction and regurgitation—but to anyone who is familiar with the characteristic sound of an aortic regurgitant murmur the difference ought to be manifest. The changes in the heart and in the circulation which follow from a double aortic lesion are quite different from those in a patent ductus arteriosus case.

We return to our patient with the evidence of a congenital heart lesion and his puzzled doctor. The first comforting fact is that if the boy has reached the age of 12 or 15 years, the congenital lesion cannot have been very severe, for if it had the boy would have died in early life. The mortality associated with congenital heart disease is very high during the first five years of life, either from cardiac failure or defective circulation. So that the fact that the patient has passed through childhood successfully is a hopeful sign.

The doctor will next make a general survey of his patient from the point of view of his physique and development. If he finds that the boy has grown normally and has the development suitable to his years, he may also be reassured as to the degree of congenital defect. It may be laid down as a general law that if any vital organ has had its functional capacity impaired from the time of birth there will follow a corresponding defect in the normal general development of the body. This condition, known as infantilism or dwarfism, is seen as the result of congenital disease (with impaired function) of the liver, the intestines, the pancreas, the kidneys, the lungs, and the heart. Hence if we find our young patient normally developed, we have an indication not to form a gloomy prognosis.

Another question to be settled is, What sort of life has the patient been able to lead? Has he led the ordinary life of childhood, or has he been unable to engage in the games and exercises of his companions? If the parents are unaware of any disability, or if the boy has been leading an ordinary life, then we have most important evidence as to the small significance of the congenital lesion. You may count as of no importance the presence of a murmur, however loud it may be, if the boy holds his own at cricket and football. If there has been no disability of the heart from the functional point of view, you will probably find no evidence of dilatation or hypertrophy in the ventricles, or any physical change in the heart other than the murmur.

On the other hand, there may have been noticed a certain limitation in the patient's ability to undergo any active or prolonged exertion within the normal powers of his years. In such a case you will probably find some change in the size of the heart, usually in the shape of hypertrophy of the right ventricle, sometimes of both ventricles. When there is a difficulty in supplying oxygen in sufficient amount to the tissues as the result of a congenital lesion there will be some compensatory change in the heart, manifested as hypertrophy, or in the blood, manifested as polycythaemia. When the compensation is complete, as sometimes happens, there will probably be no symptoms of functional disability. When the compensation is not quite complete, as more commonly happens, there will be a corresponding limitation of the patient's powers owing to functional inefficiency of the heart.

If these views be accepted the indications as to the lines of treatment will be clear. The boy who has no symptoms and who has been leading an ordinary life will be allowed and encouraged to continue doing so. The boy who has found certain limitations to the amount of exercise he can take and strain he can undergo will be advised to keep well within those limits. More especially are competitive struggles with healthy boys to be discouraged. His life race must be run at a slower pace and with a certain time allowance. Record breaking is not for him. If we are guided by the symptomatology in these cases our treatment will probably be much more beneficial to the patient than if we concentrate on the problems presented by the cardiac murmurs.

## 2. THE ASTHENIC HEART.

I have applied the term "asthenic heart" to a very common condition in adolescence. It is not a disease, but a developmental form of general asthenia which may manifest itself by symptoms ascribed to a weak heart.

My typical example of this condition is that of a boy or girl for whom medical advice is sought because of fainting, or palpitation, or temporary loss of consciousness, or sudden changes in colour—turning white or flushing suddenly—or pain about the precordial region. Alarm has been caused by the presence of one or more of these symptoms, and the home diagnosis has been some form of heart trouble.

Now we have here a serious problem—to say whether a heart is sound or not. All of us can detect well marked disease of the heart with great ease, but when it comes to the decision as to the absence of any disease the problem is much more difficult. One fact may be kept in mind here—that while in advanced life we often find symptoms of organic disease without marked physical changes in the heart, during adolescence we are not likely to meet with serious heart disease which is not evidenced by clearly defined physical changes in the heart. Before dealing with the examination of our patient's heart let us consider the symptoms which have excited alarm.

In adolescent life organic heart disease may or may not be accompanied by symptoms. The symptoms when present are usually definite and traceable to the heart. In patients who are going about they are—shortness of breath on exertion, a disinclination to make the exertions which are a pleasure to healthy companions of their own age, and a feeling of tiredness after moderate exertion. These symptoms are quite compatible with heart disease, and to the medical mind they suggest it. You will note, however, that our type patient here has not been brought because of these symptoms. Faintness and fainting, loss of consciousness, sudden changes of colour, and chest pains—these are not suggestive of organic disease in young people who have been leading an ordinary life. I go farther and say that so far as my own experience goes a history of one or more of these symptoms is *prima facie* evidence that the boy has not heart disease. You are all familiar with the type of boy or girl who faints at school when standing up. The vasomotor tone is low and the cardiac

tonus is not fully developed. This is the type of case we are dealing with, and the other symptoms are to be similarly explained. So that in dealing with symptoms which have caused alarm in the family circle and led to a diagnosis of heart disease do not be misled, but consider carefully whether the symptoms are really cardiac and whether they cannot be explained as having another origin.

The patient's heart must be examined, and here it must be admitted difficulties often arise and differences of opinion appear. There are certain changes in the heart which some will pronounce to be pathological and which others—including myself—will declare to be within physiological limits. The common changes noted are: (1) an increase of the heart rate; (2) an irregular action of the heart; (3) the presence of dilatation, usually of the left ventricle; (4) the presence of a systolic murmur at the apex.

(1) *Increased Frequency of the Heart Rate.*—While no one will be alarmed by an increase of rate up to 100 beats a minute, when one finds a rate of 120, or 140, or even 160, as I have found it, there is apt to be suspicion as to serious disease. The rapid heart in those cases is, however, the result of nervous disturbance and instability. The owner of the heart which runs off at the rate of 140 will show other evidences of nervous instability, more especially on the sympathetic and emotional side. Endocrinologists would no doubt supply information as to the exact hormone which is wanting or is in excess. You will find that the heart rate varies much from time to time, but when the patient is asleep it is always normal. This does not happen in hearts which are toxic or suffering from active organic disease.

(2) *Irregular Action of the Heart.*—A sinus irregularity of the heart, if the action is slow, is very common and is dependent on respiration. Extra-systoles may occur at times. When there is a combination of these two irregularities—a compound irregularity, as I have called it—the result is rather puzzling to one unaccustomed to the irregularity. It should always be kept in mind that the serious irregularities of the heart beat, such as those associated with auricular fibrillation, auricular flutter, heart-block, etc., are extremely rare during adolescence. On the other hand, the above forms are quite common and can usually be recognized by making the patient hold his breath. During the period of breath-holding the sinus irregularity will disappear entirely, and the extra-systoles will present their characteristic features, which are easily recognized. It may be stated definitely that neither of these irregularities is of any significance or importance, as they occur quite commonly in the absence of any organic disease of the heart.

(3) *Dilatation.*—If a medical man believes that the youthful heart must lie in a certain position and within the prescribed geographical limitations of the textbooks, he will find pathological dilatation common in these patients. Having found it on one occasion he will probably order some months' rest in bed—irrespective of the fact that a little exercise would probably have brought it within his normal standards. If, on the other hand, he recognizes—as is the case—that the youthful heart lies in many different positions, and that the apex is a very variable point, he will not be much concerned at finding the apex beat in the fourth intercostal space and half an inch outside the nipple line. He will examine the patient standing up and lying down; after rest and after exercise; and he will note many changes in the shape of the heart. In the type of case we are dealing with there is no doubt that these physiological variations are strongly marked. The displacement of the apex outwards and to the left is often very striking. Equally striking is the way it may come in again as the result of any strain thrown on the heart, such as a smart run or drawing deep breaths. I cannot help thinking that in such patients full inflation of the lungs has a striking effect in bringing the heart back to "normal" limits. If, on the other hand, one is dealing with dilatation due to organic heart disease, it will be found that the position of the apex does not change in the same way as the result of exercise or full respirations.

(4) *The Presence of a Systolic Murmur.*—A soft systolic murmur is often audible at the apex and may give rise to unwarranted suspicions of heart disease. In this connexion it is well to bear in mind that a slight degree of mitral regurgitation is never the cause of cardiac symptoms in a young person. The murmur, like the dilatation, is subject to great variation from time to time, and under changing conditions of rest and exercise. Both are probably dependent on the atonic condition of the heart. The ventricles are not contracting and the valves are not closing with their usual

smartness and efficiency. Hence at times a slight reflux takes place through the mitral valve, and a systolic murmur becomes audible. The important point is that we have no clear evidence here of valvular disease, and systolic murmurs at the apex, apart from definite valvular disease, may be safely ignored in the case of young people.

We have thus failed to find any convincing evidence of the presence of serious heart lesion. At most we have made out signs of cardiac flabbiness and instability—a very different condition from organic disease. If we extend our examination to the rest of the circulatory system we shall probably discover evidences of a lowered vasomotor tone. The extremities are often cold and dusky, and chilblains are commonly present in the winter months. The pulse is soft and weak and of low tension. If we feel it at the wrist with the arm pendent it may appear to be fairly good, but if the hand be raised above the head the pulse falls away or disappears entirely. This is in marked contrast to the pulse in a healthy youth, which maintains its good tone in any position and irrespective of gravity. Functional or postural albuminuria is often present as the result of vasomotor instability.

If we extend our examination of these patients still farther we shall find that it is not only the heart and blood vessels which are asthenic, but that other muscles in the body are lacking in tone. The stomach and intestines are atonic. Splashing is often elicited in the stomach many hours after a meal, due to atonic dilatation. The muscles of the abdominal wall are flabby and atonic. So general are these evidences of muscular weakness that we are led to assume a nervous cause rather than a purely muscular condition. There is as the basis of the varied symptomatology an underlying state of nervous instability and immaturity. Whether time will show that this is also traceable to some endocrine defect or not I cannot say definitely—it is quite possible. But there is no doubt, from the period of life at which the symptoms show themselves, that the condition is largely a developmental one, tending to come on at the age of puberty and to pass off when the patient has reached adult development. In some cases it does not pass off, and if the subject has joined up and been accepted for the army, after a period of strain he will be discharged as suffering from "soldier's heart."

As regards treatment, if the symptoms complained of are not cardiac in origin, and if signs of organic disease of the heart are absent, do not acquire the reputation of being a careful doctor at the expense of the patient's future—by treating him as suffering from a weak heart. If you accept the views given above you will agree that the very worst policy to pursue is to make invalids of these subjects by guarding and treating their hearts. Such a policy has in the past cut short many a promising career. Patients of this type are to be encouraged to lead an active open-air life, and their ordinary routine is only to be regulated so far as to protect the underdeveloped powers from undue stress and strain.

### 3. THE ATHLETIC HEART.

A somewhat allied condition is described and known as an "athletic heart." After some more than usually severe game or other exertion a boy has fainted or complained of severe precordial pain. He is said to be suffering from a strained heart. Now I do not wish to deny the possibility of the heart of a healthy boy being strained as the result of exercise, but I do say that I have never met with a case. I have met with many cases in which the heart was said to have been strained, but in all cases some other explanation presented itself. In some cases a damaged heart was present, the result of organic disease, which had been latent as regards symptoms until a breakdown occurred. I recall the case of a young miner who was said to have injured his heart as the result of lifting a heavy piece of coal. He became breathless and suffered from palpitation, and the doctor who examined him found that he had strained his heart. He drew full compensation for this for twelve months, at the end of which time I saw him. There was well marked mitral stenosis with hypertrophy of the right ventricle. By no stretch of imagination can mitral stenosis be induced by physical strain. This young fellow had certainly had rheumatic valvulitis some ten years previously, with the gradual development of stenosis in the mitral valve, but with compensation fully maintained until a severe muscular effort broke it down. This is one type of the so-called strained heart to be met with. In other cases so described I have failed to find any evidence of injury or strain. The diagnosis has been made either on the symptoms described in the last section—

palpitation, faintness, etc.—or in some slight deviation from normal on examination of the heart; such as dilatation; rapid action, etc. Perhaps it is dilatation of the heart that crops up most frequently as the result of this so-called heart strain. Now dilatation of the heart is an evidence not of strength but of weakness. It is never found to occur without some definite cause, such as organic heart disease or severe general illness. But heart strain is said to occur when neither of these conditions is present—in a presumably healthy lad undergoing the ordinary exercises suitable to his age. If you can imagine the Oxford and Cambridge boat crews being set to compete against each other twice a day for weeks on end, you might find that cases of dilatation from cardiac debility appeared. But no one would think of suggesting such a strain—one race a year suffices. In the case of schoolboys, a competition may lead to one entrant falling out exhausted before the race is finished, but he does not strain his heart. Why? Because the heart is very well able to protect itself, makes its own adjustments under conditions of physical stress, and when it has had enough produces in its owner sensations of breathlessness, precordial pain, or exhaustion, which make him pull up. I do not deny the possibility of a healthy youth producing a condition of injurious strain in his own heart, but I think all the chances are very much against it, and I have not so far met with a case. Consequently I do not find that the problems of a strained heart in youth are very difficult of solution.

#### 4. ORGANIC HEART DISEASE.

It was suggested to me that I might give you an address to-day on cardiac murmurs. Heaven forbid! I hope that none of you has to mourn over years misspent in the unprofitable study of cardiac murmurs, as I have. Who was it who gave the death blow to this futile pursuit? It was James Mackenzie, a general practitioner in Burnley, who evolved the real methods of cardiac examination, discovered many hidden secrets of the cardiac mechanism, and pointed out the lines of further and progressive investigation. Mackenzie has always held that murmurs have to be considered in any examination of the heart, but he has also shown that they do not hold that position of importance which had been accorded them.

For practical purposes we may divide murmurs into two classes: first, those that count, and secondly, those that do not count. This applies very well to the adolescent period of life.

By the term "murmurs which count" I mean those that are indicative of serious valvular disease, and most commonly of lesions which lead to progressive cardiac change and cardiac disability. The murmur in itself is nothing. The questions it raises—Has the underlying lesion produced any changes in the heart? and Are those changes serious and likely to be progressive?—are everything. A murmur is a clue which has to be followed up, if it bears evidence on the face of it that there is something behind. The two chief murmurs falling into this category are the presystolic murmur of mitral stenosis and the diastolic murmur of aortic regurgitation. They claim notice because of their frequency and their importance. During adolescence a presystolic murmur tends to alter and become louder because the initial lesion of childhood, mitral valvulitis, has induced a progressive narrowing of the mitral valve. As the youth grows, the heart should also increase in size, and the mitral valve should become larger. But the process of stenosis which has begun prevents this enlargement of the mitral opening, and thus the work of the right heart is increased. The diastolic murmur of aortic regurgitation is quite common, much commoner than is usually stated and believed. This is because it is easily overlooked unless one is always on the watch for it. Either of these murmurs may be present at this age without any symptoms—that is to say, the patient may be leading an ordinary life and unconscious of any cardiac disability. This is all to the good, but a careful examination of the heart for secondary changes is none the less necessary. It is on the symptoms present and on the secondary changes in the heart that our immediate prognosis and treatment are based, and not on the mere presence of the murmur. These, then, are the two chief murmurs which count. Expressed in other words, it may be said that it is the murmurs which are diastolic in time that count. Compared with these two in frequency, the other murmurs which are of importance, such as an aortic systolic murmur, are so rare as not to call for consideration here.

By the term "murmurs that do not count" I mean the systolic murmurs common at the apex and the base, often

suggestive of mitral incompetence or of a lesion of the pulmonary valve; often soft and indeterminate as to whether they are produced inside or outside the heart; and often puzzling as to whether they signify anything or nothing. That is why I call them murmurs that do not count. They are not worth worrying about. However exact the diagnosis, one learns nothing from the murmur as to prognosis, which will be decided by the presence or absence of other changes about the heart, indicative of a valvular lesion.

In the solution of our cardiac problems I think one simple method of examination is too much neglected—namely, palpation. At the age we are considering it is much more applicable than in later years when fat breasts and thick chests make precordial palpation of little use. In adolescents we can make out the cardiac boundaries by palpation and percussion with great accuracy and we can determine definitely the presence of two most important conditions—namely, dilatation and hypertrophy. Personally I learn much more about the condition of the heart from palpation than I do from auscultation. By auscultation one learns what noise a valvular lesion is producing; by palpation one learns what effect the lesion is producing on the heart. Some doctors, beginning with auscultation, receive such a shock on hearing a murmur that they make no further examination. Let me illustrate my point.

A young patient was found to have a heaving apex beat, outside the nipple line, and indicative of hypertrophied action. There was no murmur audible and no evidence of heart disease apart from the hypertrophy of the left ventricle. The radial artery was hard and thickened, and the blood pressure was 160 mm. The urine was of low specific gravity and polyuria was present. Further examination showed the presence of bilateral cystic kidneys, which explained the vascular changes, and the ventricular hypertrophy noted on palpation.

A child suffered from a succession of attacks of precordial pain, cyanosis, rapid heart action, and collapse. These attacks were looked on as cardiac in origin, but on routine examination nothing abnormal was detected. There was a soft systolic murmur audible at the apex and the base but no evidence of valvular disease. Careful palpation showed an area of pulsation at the base of the heart, strong and suggestive of aneurysm, and on percussion the basal dullness was found to extend up to the clavicle. A diagnosis of aneurysm was made—there seemed no other possible diagnosis—and at the autopsy a large aneurysm of the pulmonary artery was found.

Palpation does not always settle cardiac problems, but it may do good in raising them. For instance, suppose that on palpation a definitely hypertrophied action of the left ventricle, with extension outwards of the apex, is felt. It is clearly our duty to search for some cause in the heart or in the circulation for this hypertrophy. If on auscultation a murmur, systolic in time, is heard at the apex, some are content to accept this as a sufficient explanation and to label the case one of mitral incompetence. This may be correct in some cases, but in my experience it is not common in the case of these young people to find mitral regurgitation leading to great hypertrophy of the left ventricle. Before accepting this as a complete explanation I would ask you to examine carefully for two other cardiac lesions. They will not probably both be present, but one or other will serve as a sufficient explanation. The one is aortic regurgitation, manifested by a diastolic murmur, heard either at the apex or along the left side of the sternum. The other is pericardial adhesions, usually between the pericardium and the chest wall, and tying down the ventricle to such an extent that it can only carry on the circulation by hypertrophy and dilatation. Either of those conditions will produce an amount of hypertrophy which is seldom met with in pure mitral regurgitation at this age, and one or other of them is usually present in such cases, although very easily overlooked. In the same way when we find enlargement and pulsation well to the right of the sternum, we must try to find some lesion which will explain this abnormality. It may be the result of mitral regurgitation but it usually is not. The commonest causes here are mitral stenosis or pulmonary stenosis, which should be carefully looked for. You will find that auscultation and palpation are mutually helpful—auscultation in that it leads one to seek for changes in the heart which result from the lesions which produce murmurs; and palpation in that it shows changes in the heart which lead one to seek out the lesions causing them.

#### TREATMENT.

The treatment of heart disease during adolescence has certain problems of its own. Perhaps the chief is the prevention of further rheumatic infection. Acquired and chronic

heart disease in early life is the result of acute rheumatic infection—for all practical purposes other causes may be left out. The danger of fresh infection or the recrudescence of latent infection persists as a real one all through adolescence. Sometimes this will take the form of an acute flare-up—acute rheumatic fever; in other cases it will be manifested by slight pains in joints or tendons or muscles, symptoms which do not incapacitate the patient but are unfortunately often accompanied by fresh endocardial and myocardial inflammation. Consequently my own practice is to treat those patients all through adolescent life with sodium salicylate. This need not be given continuously, but for a week or ten days in every month the patient should take from 40 to 60 grains of sodium salicylate daily. This is the best preventive treatment of further infection which I know.

Those patients who have a cardiac lesion but who present no symptoms under the ordinary routine of life had better be left alone so far as any heart treatment is concerned. In giving advice about their future life and work one will naturally select some occupation which does not involve great physical strain.

Those patients who have a cardiac lesion and who find that any extra exertion induces symptoms such as breathlessness had better be advised to observe their own limitations. Games and exercises should be regulated so as not to tire out the patient or produce cyanosis and breathlessness. In selecting a suitable occupation for their adult life it will probably be best for them to take up work of a sedentary nature so that the exercise they take may be independent of their work and not part and parcel of it.

Those patients who have a cardiac lesion accompanied by breathlessness and distress on any exertion do not require to be specially restricted. Nature will teach them to go slow and not to do themselves harm. They have permanently damaged and disabled hearts.

During adolescent life there is less call for direct treatment of the heart than either before or after. This is fortunate, for it spares me the trouble of going into the nature of efficient and direct cardiac treatment. I am afraid I should only have exposed my own want of knowledge of the whole subject of cardiac tonics and my utter scepticism as regards most of them. No one has yet discovered a tonic which will improve the action of a heart which has hypertrophied in order to overcome some permanent difficulty. No one has yet discovered a tonic which will restore that heart when once the muscular power has given out. The more one studies the action of the heart in health and in disease the more one is struck by its wonderful power in accommodating itself to meet the ever-varying calls of the circulation, and in overcoming the difficulties and new problems introduced as the result of disease. Of all the self-regulating mechanisms in the human economy there is none which surpasses the heart in the power of meeting difficulties in health and developing compensatory changes in disease. These inherent powers of producing compensatory changes in the heart, largely through hypertrophy of the cardiac muscle, are specially manifested during adolescence and are not to be relied on to the same extent in adult life.

We can ease the work of a diseased and labouring heart by giving it partial rest. We can remove all physical strain by keeping the patient in bed. We can cut off the sources of nervous disturbance in the brain by sedatives and narcotics. We can deal to some extent with difficulties in the circulation owing to the engorgement of other organs or the presence of oedema and effusion. These things are possible, but when it comes to be a question of direct action on the heart, treatment directed to improve the action of a failing heart, we are apt to discover our therapeutic helplessness.

Yet there is one condition in which the heart is disturbed and its action is impaired, not through the valvular lesion and not through myocardial exhaustion primarily, but as the result of an abnormally rapid rate. The cardiac force, as regards its pumping function, may be sufficient and the compensatory changes may be in working order, but the heart muscle shows signs of failure owing to the rapid rate present. If the heart rate is much increased the resting time of diastole is curtailed, and in the course of time exhaustion of the heart muscle follows. Many rheumatic hearts become disturbed at times during adolescence by the development of this rapid rate, which may be a regular action with a normal rhythm or an irregular action with an abnormal rhythm. In both of these cases it is the rapidity of the heart which is causing the trouble and which is calling for treatment. Under these

conditions we can employ digitalis with great confidence, giving full doses for a few days, and we shall often find that when the heart is slowed the patient is much relieved as regards all the signs and symptoms of cardiac failure. I do not say that digitalis will act in all cases. Unfortunately it will not, and we cannot at present tell why it slows the heart in some cases while in others it fails to do so. But it remains as our great sheet-anchor in cases of cardiac failure associated with a rapid action of the ventricles.

ON

## MAN'S POSTURE: ITS EVOLUTION AND DISORDERS.

GIVEN AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

BY

PROFESSOR SIR ARTHUR KEITH, F.R.C.S., F.R.S.,  
CONSERVATOR OF THE MUSEUM.

[Abstracts.]

### LECTURE II.—THE EVOLUTION OF THE ORTHOGRADE SPINE.

THE human spine is a mechanism of the utmost complexity; between the sacrum and the skull are incorporated twenty-four vertebrae, each provided with three short levers—the spinous and transverse processes; each lever is furnished with, not a single muscle, but a group of them. As we pass from sacrum to skull we find the levers change in length, strength, shape, and direction. The muscles, too, which move and balance the levers alter in disposition and strength as we pass from vertebrae to vertebrae. The twelve dorsal vertebrae, besides their three short processes, are provided with very long and powerful levers—the ribs. The student is so apt to concentrate his attention on the respiratory action of the ribs that he forgets that they are the most powerful of the spinal levers. All the muscles attached to ribs—the intercostals, the rectus abdominis, and oblique muscles of the belly wall—are prime movers and balancers of the spine. Here, then, is a very complex team for Nature to drive along a straight evolutionary course. By what process or processes did she succeed in transforming the multitude of spinal levers and muscles, which serve the needs of a pronograde monkey, into the forms which answer to the needs of man? Such a transformation seems highly probable if we suppose that, in the course of its evolution, the human stock has passed through two intermediate stages: (1) a *hylobatian* stage, represented by the small orthograde apes—the gibbons; (2) a *troglodytian* stage, now represented by great anthropoids such as the gorilla or chimpanzee.

### THE SACRALIZATION OF BODY SEGMENTS.

With the evolution of the upright or orthograde spine there took place a shortening of the lumbar part of the spinal column, and my first effort will be to show you the means which Nature used to attain this end. In most pronograde monkeys, both of the old world and of the new, the three vertebrae\* which become modified in the course of development to form the sacrum are the twenty-seventh, twenty-eighth, and twenty-ninth of the spinal series; Professor Wingate Todd<sup>1</sup> has given reasons for believing that the twenty-seventh vertebra formed the first of the sacral series in the earliest mammals. If one examines a number of monkeys of the same species it will be found that in some the twenty-seventh vertebra, in place of being purely sacral in its characters, shows some admixture of lumbar traits; in others, the twenty-sixth vertebra shows signs of forsaking some of its lumbar traits and adopting the characters of the first sacral. There is a tendency in some for the process of sacralization to spread in a tailward direction; in others in a headward direction. In small orthograde apes, represented by the gibbons, sacralization has spread headwards, so that the twenty-sixth now forms the first of the sacral series. In this manner a lumbar vertebra has been added to the sacrum of gibbons, giving them four sacral vertebrae in place of the pronograde three, but reducing their lumbar

\* See a paper I contributed to the *Journal of Anatomy and Physiology*, 1902, vol. 37, p. 18.

vertebrae to six in place of seven—the primitive number. The incidence of sacralization amongst gibbons is much less stable than among pronograde monkeys. In fully 15 per cent. of animals the process has spread headwards, so that the twenty-fifth vertebra shows some or all of the characters of a first sacral; over 5 per cent. of animals show a tendency in an opposite or tailward direction. Amongst the great anthropoids the process of sacralization has spread still farther in a headward direction. In the majority of chimpanzees the twenty-fifth has become the first sacral, but amongst orangs—an anthropoid type in which the lower limbs have undergone retrograde changes—the twenty-fourth vertebra (fifth lumbar) forms the first of the sacral series. In man, as in the chimpanzee and gorilla, the twenty-fifth forms the first of the sacral series; but in man the formula<sup>2</sup> is more stable than among the large anthropoids. In a series of one hundred human skeletons it will be found that some three or four will show a headward sacralization, while six or eight will show a tailward movement. The evolution of the plantigrade posture has necessitated a lengthening of the loins in man—the tendency of sacralization in him seems to be in a tailward direction.

#### SHIFTING OF LIMB BUDS.

Now the developmental process which transforms a last lumbar into a first sacral vertebra is not one which works only on bones; all the elements which lie in the same segment of the embryonic body—nerve, muscle, and vessel—undergo a transmutation corresponding to that of the vertebra. With a headward sacralization there is also a forward movement of the sacral and lumbar plexuses, although the forward shift of the nerves lags slightly behind that of the vertebrae. In point of segmental origin the buds which form the lower limbs also move forwards; so also must the centres in the spinal cord which regulate the nerve mechanisms of the lower part of the body. We cannot conceive that the process of segmental differentiation which fashions the hinder body segments of ape and of man can be influenced by any intrinsic or extrinsic agent acting on the completely developed body. The evolutionary machinery which shapes new forms has to be sought for, not in the acquired habits of the living animal, as Lamarck supposed, but in the factors which control the development of embryonic tissues, and that evolutionary machinery works in such a way as to produce new functional possibilities.

#### TRANSMUTATION OF DORSAL AND OF CERVICAL SEGMENTS.

In fashioning the lumbar region of man and of the higher primates the process of transmutation has also been at work, but to a less extent, in the body segments at the upper or dorsal end of the lumbar series. In the majority of pronograde monkeys there are thirteen pairs of ribs; the last rib-bearing vertebra is the twentieth. With the evolution of the orthograde posture in the small anthropoids the twentieth vertebra was still the last rib-bearer. In the most generalized surviving member of the great anthropoid group—the chimpanzee—the twentieth vertebra is usually the last rib-bearer; in the gorilla it is often the twenty-first; while in the orang, although it is usual to find the last rib attached to the nineteenth vertebra, yet it is not uncommon to find the process of costalization ending at the eighteenth. If we take a hundred human skeletons we shall find about two in which the eighteenth vertebra is the bearer of the last rib, ninety in which it is the nineteenth, and eight in which it is the twentieth. There can be little doubt that man's immediate ancestry had thirteen pairs of ribs; in every human embryo a vestige of the thirteenth pair appears, which subsequently becomes fused with the adjoining transverse process. The diaphragm is attached to the transverse processes of the first lumbar vertebra, representing the origin from the thirteenth pair of ribs, which is to be seen in nearly all apes. A tendency to the transmutation of the last cervical into a first dorsal or a first dorsal into a last cervical is to be recognized both in man and apes. But in apes, as in men, it is much commoner to see the last cervical vertebra assuming dorsal characters than the first dorsal assuming cervical characters. The tendency of the dorso-cervical movement, which is slight, is in a headward direction. There is no reason to suppose that in the evolution of the higher primates there has been an intercalation of new segments at any point of the vertebral series; segments have been shed, but always it is the hindmost segments of the body which disappear.

#### WHY THE LOINS WERE SHORTENED.

What, then, is the functional significance of the shortening of the lumbar region which has taken place with the evolution of the orthograde posture? Why should this region be again elongated and strengthened when the human body became adapted to the plantigrade posture? In pronograde monkeys of the old world the lumbar part forms from 40 to 45 per cent. of the presacral spine; in small orthograde apes the lumbar region varies from 30 to 34 per cent. of the spine. I have already drawn attention to the fact that pronograde apes gain their forward impetus in leaping from their hind limbs; in the act of springing the thoracic part of their bodies is raised by extension of the loins; the lumbar part of their spine serves as a flexible lever for moving the upper part of their body on the fixed pelvic base. In the orthograde gibbon the lumbar region serves quite a different purpose. As the arms are the main organs of progression the lumbar part of the spine serves chiefly as a flexible lever for attaching the pelvis and lower limbs to the body; in its forward flight branches are seized by the feet for support and thus the weight of the body does come to rest temporarily on the lower limbs of the moving gibbon. Its lumbar spine serves alternately as a suspending and a supporting lever. The change from the pronograde to the orthograde posture was attended by a shortening of the lumbar region, brought about by the sacralization of the twenty-sixth body segment. There was at the same time an enormous saving in muscular expenditure. This will be evident when I lay the following observation, made on healthy jungle animals, before you. In a pronograde monkey I found that the muscles employed in extending the spine—the erector spinae group—weighed 93.5 grams, while in the orthograde gibbon, although the weight of its body was rather more than that of the monkey, the erector spinae group weighed only 44.2 grams—less than half the weight of the pronograde musculature.

#### THE LUMBAR CURVE.

With the evolution of the great anthropoid type the lumbar region of the spine became still shorter and stronger. In the chimpanzee the lumbar part, on an average, forms 27 per cent. of the presacral spine; in the orang only 24 per cent.; in the gorilla rather more—namely, 29 per cent. In none of the great anthropoids is the whole weight of the upper parts of their bodies transmitted through the lumbar region of the spine except momentarily. In its climbing movements the chimpanzee makes an equal use of its upper and lower limbs in supporting its weight; in the orangs the upper extremities are the predominant supporting—or rather suspending—organs for its natural arboreal progression; in gorillas the lower extremities are more specialized than the upper for purposes of support and movement. With the evolution of the human or plantigrade posture the lumbar region of the spine became further modified and strengthened to form a flexible lever on which the whole weight of the upper part of the body is poised. An easy and graceful carriage of the human body requires long loins. At birth the lumbar region measures 27 per cent. of the presacral spine—the same proportion as in the chimpanzee. Elongation takes place rapidly as a child learns to walk; in the average adult the lumbar region comes to form about 32 per cent. of the total length of the spine. Indeed, it is not too much to say that the spine of the human baby, as regards the proportions of its parts and its curvatures, is in an anthropoid or troglodytic phase of evolution. We have only to watch an infant trying to support its body erect when learning to walk to see reproduced the orthograde posture of a great anthropoid ape. The lower limbs are seen to be imperfectly extended, the body plainly inclines forwards, and the arms stretch out to clutch at neighbouring objects for support. In the second year of life, growth changes in the lumbar vertebrae make further extension of the body a permanent possibility; it is then that the loins elongate and the lumbar curve, seen only in the human species, makes its appearance.

#### ALTERATIONS IN THE MUSCULATURE.

When we compare the spinal musculature of a pronograde monkey with that of the various orthograde forms, including man, we are struck by the simple nature of the structural modifications which have served to adapt the pronograde system of muscles to orthograde purposes. Not a single new muscle has been introduced; everywhere we meet with the same series of vertebral levers and the same groups of muscles acting on them. The brunt of the evolutionary or

adaptational changes has fallen on the spinal musculature of the lumbar region. True it is that certain changes take place in the muscles which extend the dorsal part of the spine, but the moulding of the dorsal region has more to do with respiratory purposes than for the mere support of the body in an upright posture. The musculature of the cervical region also undergoes certain changes with the evolution of the orthograde forms, but the chief transformations seen in this region of the spine do not depend on postural adaptations, but on jaw and tooth development. The neck is the movable lever of the head; if there are massive jaws and great teeth then must the skull be widely hatted to a strong and thick neck. There is a growth mechanism which correlates the development of neck and jaws.

#### ESTABLISHMENT OF A PELVIC BASE.

We turn, then, to note the chief changes which have taken place in the spinal musculature of the loins of higher primates; they provide a series which lead from the condition seen in pronograde monkeys to that seen in orthograde, plantigrade man. As we pass along the series we note that the spinal musculature obtains an ever-increasing attachment to the sacrum and to the pelvis; the pelvis becomes more and more a fixed base from which the erector spinae may act. The steps which led up to the great pelvic base of man were the following: (1) With, or before, the assumption of the orthograde posture, the tail as a free external organ completely disappeared; in every member of the orthograde the tail vertebrae have become submerged and coccygealized. The disappearance of the extensors of the tail leaves the dorsal surface of the sacrum free for the use of the erectors of the spine. (2) The sacralization of the seventh and then of the sixth lumbar vertebra extends and strengthens the area for spinal fixation. (3) An enormous extension of the iliac crests, particularly in a dorsal direction, gives an increased base for fixation of spinal muscles. The dorsal extension of the iliac crests reaches its climax in the human pelvis. In the gibbon the ilium and its crest are shaped much as in monkeys; the transformation has become marked in the great anthropoids, the gorilla showing the nearest approach to man in the development of its iliac crests. (4) In man the area for muscular origin is also increased by the backward tilting of the sacrum, so that its dorsal surface in the erect position looks upwards as well as backwards.

#### SPONDYLOLISTHESIS.

This oblique, in many individuals almost horizontal, position of the human sacrum deserves our particular attention. Everyone must have observed how variable is the depth of the curvature of the loins; in some individuals the sacral aspect of the pelvis forms almost a horizontal shelf. In certain races, particularly negro and negroid, the loins are straight; the sacrum seems to almost continue the line of the lumbar spine; in other races, particularly in Europeans and more in women than in men, the sacrum forms almost a right angle to the lumbar spine. The spine, transmitting the weight of the suprapelvic part of the body, is poised on the anterior or basal end of the sacrum. The weight tends to tilt up the hinder or coccygeal end of the sacrum, and would do so were it not for (1) the form and strength of the sacro-iliac joints, (2) because the hinder end of the sacrum is bound to the ischial tuberosities by those particularly strong stays, the sacro-sciatic ligaments. There is also a tendency, when the sacrum is set obliquely, for the basal end of the spine to be dislocated forwards into the pelvis, giving rise to the condition known as *spondylolisthesis*. Such a dislocation is prevented by the articular processes of the last lumbar vertebrae being locked within those of the sacrum. A sudden jump, or severe effort to lift or carry a heavy weight, may cause the laminar arch of the last lumbar vertebra to snap and thus permit a forward displacement of the spine. I know of no evidence which leads me to suppose that the separation of the arch of the last lumbar vertebra is the result of maldevelopment.

#### ADAPTATIONS FOR LATERAL BALANCE.

We have been discussing the evolutionary changes seen in the sacrum and pelvis of apes and men—changes which were required to give a more extensive and firmer base from which the erector muscles could act. We note that the pelvic base becomes wider. The reason for this is quite clear. The spine of a pronograde monkey, if converted to serve the needs of the orthograde posture, will require special adaptations, not only for extension and flexion, but also for lateral movements

and balance. As the ribs are by far the most powerful lateral levers, it was by a modification of them, and of the muscles acting on them, that lateral balance in the orthograde posture was secured. The thorax was transformed in shape, not for respiratory but for postural purposes. Every costal arc is made up of three segments—a dorsal, to which the spinal muscles are attached; a lateral, which is acted on by the intercostals and oblique muscles of the belly wall; a ventral or anterior segment, to which the rectus abdominis is inserted. Every muscle attached to a rib is also a spinal balancer. With the evolution of the orthograde posture one notes that the dorsal segments of the ribs became increased in length, thus giving the spinal muscles a greater lateral purchase on the spine. Further, they became set farther back—more on the plane of the tips of the spinous processes—thus giving the muscles attached to the dorsal segments of the ribs a greater power in extending the spine and keeping it erect. Thus, in the orthograde types the bodies of the dorsal vertebrae have the appearance of being pushed farther within the cavity of the thorax than in pronograde types.

#### THE ORTHOGRADE ADAPTATIONS SEEN IN SPINAL MUSCLES.

In the course of a single lecture it is impossible to give a detailed account of all the changes which are seen to take place in the spinal musculature with the evolution of the orthograde posture. But I may cite one or two instances to illustrate the manner in which evolutionary changes are effected. The quadratus lumborum of man is a lateral balancer of the spine. It rises from the iliac crest and is attached to the transverse processes of the lumbar vertebrae and to the last rib; some of the fibres to the last rib rise from the transverse processes. The quadratus of the great anthropoid apes is similar in form and action to that of man. In pronograde apes this muscle forms a series of fasciculi acting on the transverse processes of the loins; the hindermost of these springs from the iliac crest; the most anterior end on the last one or two ribs. The fasciculi adjust the lumbar vertebrae by acting on their transverse levers. The quadratus of the gibbon is, as regards form and action, intermediate to the stages seen in monkeys and great anthropoids. Evolution has proceeded by combining a series of independent fasciculi, acting individually, to form a single muscle which acts on a region of the spine rather than on individual vertebrae.

The changes which came over the deepest layer of the spinal musculature—particularly in the muscle known in human anatomy as the multifidus spinae—were of a similar nature. In the great anthropoids we find the spinalis dorsi assuming the form seen in man. With the evolution of the orthograde posture not a single new muscle was introduced in the spinal series; yet all became modified, some to a slight extent and some to a great extent. But in all cases the machinery of evolution is the same; it consists of partial or complete migration of muscular attachments; a fusion or separation of fasciculi; under- or over-development of the various constituent parts of a muscle.

#### THE COMPLEXITY OF THE PHYSIOLOGICAL PROBLEM.

It is when we concentrate our attention, not on the anatomy but on the physiology of the spinal musculature that we realize the complexity of the problem implied by the evolution of the orthograde posture. In pronograde mammals, be they four-footed or four-handed, each vertebra has to be adjusted by muscular action so long as the animal sits, walks, or stands. In orthograde primates each vertebra has to be balanced on another, so long as the erect or semi-erect position is maintained. Their thick intervertebral discs make balance more delicate. A little sum in arithmetic will help us to understand what a living vertebral balance means. In the spine of the commoner kinds of monkeys there are twenty-six vertebrae; each is provided with three short levers; thirteen of them have in addition the long and powerful costal levers—104 levers all told. On an average four muscles act on each lever—416 muscles in all. From each of these muscles constant streams of impulses are passing into the nerve centres of the cord and equally constant streams are emerging to maintain the postural tone and actions of the muscles. Besides these streams of afferent and efferent impulses there are the equally extensive higher streams flowing to and from the postural centres of the mid-brain and the timing mechanisms in the cerebellum and bulb. The nerve centres of the spinal cord, mid-brain, and hind brain of a monkey are organized to carry out the reflexes necessary for a pronograde posture. It is habitual for monkeys of all kinds to assume a sitting or semi-erect posture when

resting; to maintain this attitude the nerve mechanisms must have in them a nucleus which may have been expanded into that elaborate mechanism which serves the needs of orthograde apes.

#### SCOLIOSIS.

In none of the orthograde forms is such a continuous and urgent demand made on the postural spinal mechanism as is the case in man. In man only is the whole weight of the suprasacral part of the body supported erect on the spine over long intervals. The demand on this neuro-muscular postural mechanism is, I think, even greater in the sitting than in the standing posture, particularly if we sit leaning forwards in writing and reading. Sitting bolt upright is particularly exhausting, more especially for young people in whom growth of vertebrae and of spinal muscles is proceeding apace. The muscles which act on the short levers of the spine yield first, while the muscles which act on the long costal levers can still keep on. We rest these exhausted short spinal muscles by allowing the vertebrae to rotate until the articular processes begin to lock and the transverse processes rest upon the necks of the long costal levers. Herein lies the beginning of lateral curvature or scoliosis. If the habit becomes fixed, then come the deformities of chest, vertebrae, and spine with which orthopaedic surgeons are only too familiar. It is not true, however, to say that our spines are not perfectly adapted to the upright posture; it would be more accurate to say that human spines were not evolved to withstand the monotonous and trying postures entailed by modern education and by many modern industries.

### The Goulstonian Lectures

ON

## THE NATURE OF ARTERIO-SCLEROSIS.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS  
OF LONDON

BY

GEOFFREY EVANS, M.D. CANTAB., F.R.C.P. LOND.,  
ASSISTANT DIRECTOR, MEDICAL UNIT, AND ASSISTANT PHYSICIAN,  
ST. BARTHOLOMEW'S HOSPITAL.

### LECTURE II.—THE INTRINSIC PROCESS IN ARTERIO-SCLEROSIS.\*

THE histology and distribution of diffuse hyperplastic sclerosis formed the subject of the last lecture. The nature of the process concerned in the development of the lesion is the next aspect of its pathology to be considered. From a theoretical standpoint one or more of four cardinal processes are involved—namely, Involution, Growth, Inflammation, and Degeneration. The subject is a difficult one to present concisely, and if it is dealt with from an abstract point of view its presentation is liable to be either too dogmatic or ambiguous; hence I have chosen a chief advocate for each theory, and will discuss the theory on the basis of the argument and facts brought forward to support it.

#### PHYSIOLOGICAL PROCESSES.

##### (a) *The Process of Involution.*

Thoma's<sup>1</sup> view of arterio-sclerosis was based on the observation of the changes that take place in the aorta at birth on the interruption of the placental circulation. He observed an intimal thickening of the aorta between the origin of the ductus arteriosus and the origin of the umbilical arteries, due to cellular proliferation and new formation of connective tissue in the subendothelial layer, and, as Jores showed later, due also to the formation of elastic tissue in this layer. Thoma compared this change to the intimal thickening found in ligatured arteries and in the obliterated hypogastric arteries of infants, and he attributed it to a slowing of the blood stream. He applied this theory to the development of arterio-sclerosis. Thus, in the case of nodular sclerosis, he held that the intimal thickening was secondary to weakening of the media,

as a result of which bulging of the vessel wall occurred, with consequent slowing of the blood stream at the site of bulging. In the case of diffuse arterio-sclerosis not due to initial weakening of the media he presumed a destruction of capillary fields by disease, and argued that as a result of reduction in the size of the vascular bed a slowing of the blood stream occurred in the vessels supplying the affected area. The theory involves the assumption that an artery may fail to adapt its lumen to the amount of blood flowing through it by contraction of the media, and that the necessary narrowing of the lumen is completed by thickening of the intima.

It is generally agreed that as a basic explanation of the development of arterio-sclerosis Thoma's theory does not hold good. Thus, as Fuchs pointed out, there is no evidence of a failure on the part of the aorta to equalize by muscular contraction the size of its lumen to the decreased quantity of blood flowing through it after cessation of the placental circulation. Further, it is inconceivable that in a system such as the cardio-vascular, which adapts itself so rapidly to changes in the distribution and quantity of blood content, a single alteration in these conditions could be responsible for intimal thickening which gradually increases over a period of years. Thoma's premisses were also shown to be incorrect by the fact that the intimal changes in the aorta are not limited to the length of the vessel between the ductus arteriosus and the origin of the umbilical arteries. Jores raised objection to the theory on histological grounds; he emphasized the fact that the intimal thickening in involution is of the connective tissue or regenerative type, whereas in arterio-sclerosis it is of the hyperplastic type—a distinction based on the different form of elastic fibres in the two conditions. Marchand also attacked the theory on histological grounds, and pointed out the absence of fatty degeneration in arterial involution in contrast to its constant presence in arterio-sclerosis. The same fact has come to my notice in studying the changes that take place in involution of the ductus arteriosus and hypogastric arteries of infants. There seemed to be an exception to the rule that fatty degeneration does not occur in arterial involution in the reported presence of fatty degeneration in uterine arteries undergoing normal involution, but, as I have shown elsewhere,<sup>2</sup> the work which led to this opinion was based on the examination of pathological material, and the fatty change observed in the specimens examined was due to disease elsewhere and was not a part of the process of normal uterine involution.

Though Thoma's theory fails in providing a basic explanation of arterio-sclerosis, it probably holds good in so far as it includes the idea of replacement fibrosis. For instance, in the case of nodular sclerosis, if the primary lesion is in the intima Thoma's theory has no application, but if the initial lesion is in the media it may well be that the intimal proliferation occurring as a secondary event is compensatory. Thoma attempted to prove that the initial change was a weakening of the media by injecting arteries affected by nodular sclerosis with melted wax equivalent to the blood pressure during life, then allowing the wax to set and cutting sections of the artery. He claimed that the nodules disappeared and the lumen of the artery so distended had a normal cylindrical form. These experiments have been repeated by Klotz,<sup>3</sup> who used water instead of wax, and cut the vessel frozen; he failed to confirm Thoma's results. Thoma also attempted to demonstrate the primary weakening of the media by injection of the vasa vasorum of the larger vessels, and he showed that a greater penetration of the media by vasa vasorum occurred at certain points where there was no intimal thickening, and since this increase in vessels in the media was found in patches of nodular sclerosis he argued that the new formation of vessels showed a damage to the media as a primary event preceding the intimal proliferation. My own view of the matter is that Thoma's view of arterio-sclerosis holds good to the limited extent that it involves the idea of a replacement fibrosis. To this extent it is in keeping with the inflammatory theory of arterio-sclerosis, and it is of this further value—that it brings out the fact that degenerative changes are a primary event in one form at least of arterio-sclerosis. Yet even when the degenerative changes are primary it cannot be assumed that the intimal proliferation is necessarily of the nature of a replacement fibrosis, since the proliferation may be a direct response to the insult that is simultaneously responsible for the medial degeneration. Thus Thoma's theory is merely an adjunct to any basic explanation of the production of the lesion in arterio-sclerosis.

\* Abstract of lecture delivered on March 8th.

*(b) The Process of Growth.*

Jores's views on the production of arterio-sclerosis may be discussed in terms of the physiological process "growth." He finds the basic explanation of the lesion in arterio-sclerosis in the intimal changes that normally occur in the aorta in the process of growth, and he expresses the opinion that "an increased functional demand on the vessel wall is a necessary factor for the development of arterio-sclerosis." He also says: "The hypertrophy of certain layers of the vessel wall and their subsequent degeneration is the essential feature of arterio-sclerosis." A distinction is drawn between this process and the process of inflammation in these words:

"In direct contrast to the thesis already advanced I regard the connective tissue thickenings of the intima as secondary events, reactions and compensatory endeavours on the part of the vessel wall, which are on a par with the phenomena of repair after injury and defect, regeneration, and scar formation processes of inflammatory reaction."

He sums up with the words:

"The development of arterio-sclerosis does not depend on these; they arise from quite other causes and do not lead to true arterio-sclerosis."

Jores bases the distinction between the hyperplastic and fibrotic layers of the intima on a study of the changes in structure of the intima of the aorta during the natural process of its growth. In the aorta in the first year of life he describes a layer on the inner side of the media consisting of two lamellae of elastic tissue lying close together; cells of variable form, in the main elongated, lie between these two lamellae. Comparing this with the aorta at the age of 13 years the same layer is seen, and now wider; the two lamellae are stronger and between them lies a fine network of elastic fibrils, while the nuclei previously seen between the two elastic lamellae have, in the majority, an obvious morphological identity with muscle cells. This is the musculo-elastic layer. It increases in thickness with growth, and though there are variations in its development the variation is within narrower limits than is the variation in thickness of the rest of the intima. At the age of 20 years the musculo-elastic layer is increased both in the thickness of its lamellae and by the splitting off of two further layers of elastic tissue from the original inner lamella. The splitting off of elastic tissue layers from the original lamellae in the process of growth of the aorta is directly compared with the same process which Jores describes as occurring in the small arteries in arterio-sclerosis. It is in this comparison of the development of the musculo-elastic layer of the aorta with the development of new lamellae of elastic tissue in small arterio-sclerotic vessels and the parallel development of the changes in the two conditions, the one of growth and the other of disease, that Jores discovers the underlying process in arterio-sclerosis.

There is, however, a difficulty in maintaining the distinction between hyperplastic intimal thickening of arterio-sclerosis and the connective tissue or regenerative thickening in the intima that is found in inflammation of arteries—a difficulty which Jores himself appreciated. The two types of intimal thickening always occur together, except in normal growth of the aorta, and as a matter of fact Jores's hyperplastic layer is often found in pure inflammatory states. [Specimens of syphilitic and tuberculous endarteritis with well formed hyperplastic intimal thickening were shown.]

A more serious criticism of Jores's views is directed against his theory of the formation of elastic tissue. He suggests that the laminae of elastic tissue in the hyperplastic layer of arterio-sclerotic vessels develop by a process of swelling and splitting of the internal elastic lamina, as distinct from the process by which elastic fibres are formed in the connective tissue or regenerative layer of the intima. Since, however, elastic fibres have no nuclei, and presumably no independent activity, the idea that an elastic lamina can grow in thickness, split and throw out thread-like branches into neighbouring tissues, is contrary to the accepted canons of biology. The present view of the formation of elastic tissue is that it is laid down by connective tissue cells or by endothelium, and, like other intercellular material, it is living but inert. Little, however, is known of the conditions that govern its formation and form, and it is an interesting speculation to draw an analogy between the formation of concentric laminae of elastic tissue in the thickened intima of sclerotic vessels and the Liesegang phenomenon,<sup>5</sup> in which banded precipitates are formed in gelatin solutions. Bradford<sup>6</sup> has shown the fundamental rôle of adsorption in the formation of these stratified layers,

and though the physico-chemical factors concerned in their formation are not yet accurately known, the influence of the surface area of the precipitated salt, the concentration of the solute and solid, the reaction of the gel and other factors have been closely studied, and may ultimately throw light on the formation of elastic tissue in arterio-sclerosis. It is evident, therefore, that Jores's theory is based on a wrong principle, and I do not think that his observations provide evidence on the proposition that arterio-sclerosis is a result of an increased functional demand made on the vessel wall.

## INTRINSIC PATHOLOGICAL PROCESSES.

The two theories of arterio-sclerosis that are more directly based on the pathological processes of inflammation and degeneration remain for consideration. The latter will be taken first, since of the four theories of arterio-sclerosis it is the most generally accepted.

*(c) The Process of Degeneration.*

Marchand<sup>7</sup> is chosen to represent this theory, as he has so far made it his own as to suggest the word "athero-sclerosis" in place of "arterio-sclerosis." Thus he states that there can be no doubt that degeneration is the main feature of arterio-sclerosis. He finds that the degeneration begins (*simultaneously with proliferation of the intimal cells*) in the deeper layers of the intima; and that the occurrence of "primary" fatty or atheromatous degeneration is so closely associated with sclerotic processes that the term "arterio-sclerosis" is not sufficiently comprehensive for the whole disease. Thoma's theory of arterio-sclerosis postulated a weakening of the vessel wall with resulting loss in its elasticity and widening of its lumen as the initial fact that determined a slowing of the blood stream. He did not, however, accept the necessity of demonstrable pathological changes in the weakened media, and inclined to the view that the more obvious degenerative changes were secondary to those anatomical changes to which he attached most importance—namely, the involuntary changes previously discussed. Marchand controverts him on this matter, and says that Thoma attached too little importance to the essential degenerative character of the processes involved. The difficulty in fatty degeneration, which the difference in the opinions of Thoma and Marchand illustrates, is as to whether it is primary or secondary; whether in fact, as Virchow pointed out, its appearance is the first sign of disturbance of tissue structure, or whether it only comes after other evidence of disturbance is visible. Marchand's views are endorsed by Andrievs, who has written, under the title of "Arterial Degeneration," "there can be no doubt that the primary histological change is a degenerative one affecting the muscular and elastic tissues."

In the case of diffuse hyperplastic sclerosis the specimens I have shown demonstrate equally beyond doubt that the primary histological change in the arterioles is proliferative and not degenerative. The interpretation of the changes seen in the parent vessels of the arterioles will depend on the significance attached to hyaline substance in their walls. I have adopted the presence of fat as my criterion of degenerative change and do not regard the presence of hyaline substance in the inner layer of the intima in these vessels as critical evidence of degeneration (Lecture I), and in this interpretation I am, I think, supported by Jores. In addition to the reasons already given for this view, it is a striking fact that the anatomical changes progress to marked extent without the appearance of fatty degeneration—in fact, fat is characteristically absent in the intima of these vessels. Hence I maintain that the lesions of diffuse hyperplastic sclerosis are primarily proliferative, and at the same time they share with other forms of arterio-sclerosis the stigma of fatty degeneration in some part of the lesion. This degenerative change is, however, secondary.

These contradictory views as to the nature of the initial lesion of arterio-sclerosis depend on the type of artery and the form of arterio-sclerosis studied, and the stage in the disease process at which the observation is made. Thus, in the case of diffuse hyperplastic sclerosis, it is only by the demonstration of the endothelial proliferation in the earliest phase of the lesion that the priority of proliferation over degeneration has been established. Klotz, on the other hand, has identified a form of arterial lesion occurring in older subjects in which fatty degeneration of the media is the primary event. This type of arterial disease will be referred to later, and in the present connexion it illustrates the fact that all forms of chronic arterial disease do not start in the same way.

(d) *The Process of Inflammation.*

Virchow's opinion<sup>8</sup> is best stated in his own words:

"In this matter I have no hesitation in completely accepting the old view and in attributing the origin of the so-called atheromatous degeneration to an inflammation of the vessel wall, and I have taken pains to show that this kind of inflammatory disease of the vessel wall is in fact exactly the same as the condition of the heart wall commonly called endocarditis. There is no other difference between these two processes than that endocarditis more often runs an acute course, and endo-arteritis more often runs a chronic course."

This is the view of arterio-sclerosis to which my own observations have led me, with this reservation—that there is at any rate one form of chronic arterial disease that begins as a primary degeneration of the media.<sup>9</sup> I have no doubt that Virchow's theory holds good for diffuse hyperplastic sclerosis, and before resuming the evidence in support of this theory it is necessary to refer to two objections that have been urged against it.

In the first place it has been urged, particularly by Jores, that the histology of diffuse hyperplastic sclerosis is different from that of lesions which are without doubt inflammatory. The difficulty of this distinction has already been alluded to, and sections of arterial lesions that are without doubt inflammatory and in which the so-called hyperplastic layer is present have been shown. Neither is it possible to make a hard and fast distinction between arterial inflammation and arterio-sclerosis on the absence of fatty degeneration in the former and its presence in the latter, since fatty degeneration may occur at a later stage in these lesions. Warthin<sup>10</sup> has pointed out the difficulty of distinguishing between syphilis and arterio-sclerosis of the aorta, and says that in the later stages these lesions can only be differentiated by the specific lesion of syphilis that he describes. In short, the comparison of the lesion of diffuse hyperplastic sclerosis with tuberculous and syphilitic endarteritis both controverts Jores's distinction between the two forms of elastic tissue formation and at the same time provides additional evidence for the inflammatory nature of arterio-sclerosis.

In the second place, it has been urged against the inflammatory theory of arterio-sclerosis that the ordinary signs of inflammation are absent; in the early stages of the lesion there is no small cell infiltration and no dilatation of the vasa vasorum. The absence of these changes in the early phases of the lesion is the important matter: their appearance later is characteristic, and due to tissue reaction to products of degeneration and necrosis. Thus Bergel<sup>11</sup> has shown that lymphocytic infiltration results from the presence of fatty degeneration in any tissue, and among other illustrations of this fact he quotes the well known small cell infiltration in arterio-sclerosis. Sir Bernard Spilsbury has drawn my attention to polymorphonuclear infiltration provoked by tissue necrosis. In addition to infiltration with lymphocytes, polymorphonuclear cells, and fibroblasts, there is a permeation of the media and even of the thickened intima with capillaries and occasionally very small arteries in well marked arterio-sclerotic lesions. These inflammatory lesions are secondary, and throw no light on the nature of the initial process.

Many authors, including Virchow and Andrewes, have called attention to the fact that arteries are relatively avascular structures, and this fact is in part responsible for the absence of the usual signs of inflammation. Thus, according to Koelliker,<sup>12</sup> all the larger vessels from 1 mm. diameter and over possess nutrient vessels which are distributed predominantly in the adventitia, in which they form a rich round-meshed capillary network, and the general consensus of opinion agrees that the tunica media of only the larger arteries and veins possesses nutrient vessels, and that these are supplied only to its outer layers; in fact, the middle and inner layers of the media and the whole of the intima are avascular structures. Inflammation of the intima may, therefore, be compared with inflammation of the cornea. Seufftleben<sup>13</sup> showed that a minimal injury to the cornea causes local destruction of the corneal cells and the appearance of a surrounding zone in which the corneal cells appear enlarged, distinct, and tumefied. The process may continue and advance insensibly to repair without the intervention of leucocytes, the hypertrophying cells of the granular zone eventually undergoing karyokinesis, and thus by multiplication replacing the cells destroyed. A more severe injury provokes the accumulation of wandering tissue cells in its neighbourhood, still without evidence of dilatation of neighbouring vessels, or diapedesis through their walls. The

absence of a primary proliferation of fixed tissue cells in keratitis and the proliferation of endothelial cells in arterio-sclerosis has no other significance than the emphasis it lays on the inflammatory process in diffuse hyperplastic sclerosis. The difference in the lesion in the two conditions may be due to the irritant acting once and for a short time in experimental keratitis, in comparison with its possibly prolonged action in arterio-sclerosis, or it may be due to the fact that whereas the corneal cells lie in an avascular medium, the endothelium, as distinct from the rest of the intima, is in a vascular medium with an abundant oxygen supply.

This distinction between the endothelium and the intima is highly important, and is supported by Grünstein,<sup>14</sup> who has published one of the best accounts of the normal structure of the larger arteries and their variation with age, and who expresses the opinion that "the endothelium does not belong to the intima, but forms an independent constituent of the arterial wall."

If this is true in fact it becomes obvious that we are dealing with inflammation in a quite peculiar structure when we consider inflammation in an arterial wall. It is a structure which is vascular in its outer layer, avascular in part of its middle and all its inner layer, and it is lined by a layer of cells which belong rather to the blood than to the vessel whose structure it is their function to form, and perhaps in pathological conditions to keep in repair.

The importance of the blood supply in determining the type of tissue changes, whether they are of an inflammatory or degenerative type, has recently been brought out in the study by Mr. A. G. Timbrell Fisher of the pathology of osteoarthritis.<sup>15</sup> He finds that the lesions are degenerative or proliferative according to the proximity of an adequate blood supply: thus in the articular surface of the knee-joint the initial lesion is a degeneration of the intercellular matrix in the central area of the cartilage—an area which is completely avascular—whereas the peripheral lesion is proliferative, due (he thinks) to the presence of an adequate blood supply from the *circulus articuli vasculosus* of William Hunter. These changes are to be compared with degenerative lesions in the depth of the intima in the larger arteries often appearing first in the internal elastic lamina, and with the proliferation of the endothelium already demonstrated in diffuse hyperplastic sclerosis, and perhaps also occurring in nodular sclerosis, as will be shown later when reference is made to the work of Klotz.<sup>16</sup>

All that is known about the function of endothelium supports the view that its proliferation in diffuse hyperplastic sclerosis is evidence of the inflammatory nature of the lesion. Thus endothelial cells have been shown to take up bacilli within ten minutes of their inoculation into the circulation.<sup>17</sup> Behring and Mutch<sup>18</sup> have called attention to the great phagocytic powers of the endocardial endothelium. In typhoid fever the endothelial cells of the spleen swell, proliferate, and become separated. There is general agreement that the large mononuclear cells of the blood have their origin from endothelial cells of capillary walls, and Baumgarten has shown that vascular endothelium under mild grades of irritation gives rise to fibroblasts and connective tissue. Adami<sup>19</sup> sums up by saying:

"We have, indeed, to recognize the very active part played by vascular endothelium in inflammation, its pronounced proliferative and phagocytic powers . . . microscopically these cells can be seen to alter during the inflammatory process; they become enlarged and project into the lumen of the smaller vessels, and in my experience this enlargement affects not only the cell bodies but also the nuclei, which at the same time would seem to contain more chromatin and to stain more intensely. In cases of chronic inflammation the enlargement is seen followed by proliferation, notably in the arterioles and capillaries, a process which may lead to the ultimate occlusion of these small vessels."

The actual form of the lesion in diffuse hyperplastic sclerosis is, therefore, strong evidence that the process of inflammation is responsible for its production.

In addition to the four main theories of arterio-sclerosis, which depend on the activity of the unit processes Involution, Growth, Inflammation, and Degeneration, it is suggested vaguely from time to time that the lesion is due to an altered nutrition of the vessel wall. This idea is crystallized by Adami in a few suggestive paragraphs dealing with the subject of productive fibroses, in which he makes the tentative suggestion that intimal proliferation in arterio-sclerosis may depend on stimulation rather than irritation, and that the nature of the stimulant may be an increased strain thrown on the intima by weakening of the underlying media, and in other cases the stimulant is an increased nutrition brought

about by heightened arterial tension. This theory turns rather on causes than processes; in its distinction between stimulation and irritation it has been considered in the review of Jores's theory, and in its reference to primary weakening of the media it comes under Thoma's theory of arterio-sclerosis. Lastly, the lesion in arterio-sclerosis has been compared to keloid, and though he does not make this comparison Ophüls<sup>17</sup> approaches this hypothesis in his reference to the autochthonous development of arterio-sclerosis. If simpler pathological conceptions fail it may be necessary to have recourse to the complicated explanations offered by the terms "productive fibroses," "fibrous diathesis," and "autochthonous development," but in the meantime I am of the opinion that the simple process of inflammation is sufficient explanation of the production of the lesion in diffuse hyperplastic sclerosis, and in the next and last lecture its activity in other forms of arterio-sclerosis will be considered.

## TREATMENT OF PUERPERAL INFECTIONS.\*

BY

B. P. WATSON, M.D., F.R.C.S. EDIN.,

PROFESSOR OF MIDWIFERY AND DISEASES OF WOMEN,  
UNIVERSITY OF EDINBURGH.

In obstetrics probably more than in any other branch of medicine old methods of treatment persist long after their efficacy has been disproved by more recent scientific knowledge and experience. In recent years our conception of puerperal infections has undergone a great change, and yet the general body of the profession has not realized it, for we daily see and hear of procedures being carried out which we can only regard as harmful.

The great danger of specialization is that the specialist is apt to lose his perspective and to be so immersed in the details of his own subject as to lose sight of advances being made in other directions, many of which may be of the utmost importance to him. What we have to realize is that the general principles of pathology have a universal application, and that the details of treatment founded upon them should require only slight modification to meet the different anatomical and physiological conditions present in any region of the body.

I do not intend to go fully into the treatment of all the different varieties of puerperal infections. All I wish to do is to ask if that treatment is always in conformity with what we know of pathology and of infections in general, for on this must depend its likelihood of yielding the best results.

Much has been learned in recent years regarding the mode of invasion of infective organisms, and nothing is of more importance from the obstetrical point of view than a realization of the frequency with which infective organisms spread throughout the blood stream from what was at first a purely local focus. The organisms concerned principally in puerperal infections—the streptococci, staphylococci, colon bacilli, pneumococci, and gonococci—very readily gain the blood stream, so that probably a few escape into it from every local focus. In the majority of instances their numbers are so small and the reaction of the blood tissues so great that they do not long survive. Furthermore, a great many organisms hitherto regarded as purely saprophytic have been proved to be capable of living in the tissues and spreading by the circulating blood. In view of these facts we must discard altogether the old classification of puerperal infections into suppurations and septicaemias. We must regard every case of bacterial invasion of the genital tract as a potential bacteraemia and must direct our treatment accordingly.

When organisms invade a raw surface the lesion is at first quite localized. There is inflammatory reaction with a certain amount of destruction of tissue. Whether the condition remains localized depends on the degree of the reaction, on the number and virulence of the organisms, and on the amount of rest that can be ensured. If spread occurs it may take place by continuity of tissue, sometimes along the surface, often along the lymph channels, or the larger lymph vessels may be invaded and the organisms disseminated in the tissues through which they run, there producing other lesions. Thrombosis of blood vessels may occur and the organisms invade the thrombus, so that it becomes more and more extensive, spreading up the veins towards the heart and to a lesser extent along the arteries. From such a thrombus the organisms may spread into the general blood stream, although this is not necessarily the case. Pieces of thrombi may become detached, and such emboli, laden as they are with the infecting organism, may set up lesions in distant parts without there being any general blood infection. Finally, without any degree of thrombosis and often with a very minute local lesion there may be a massive general dissemination throughout the blood stream—a true bacteraemia.

## CAUSE AND SYMPTOMS.

Apply this general knowledge to the particular subject. We know that the majority of infections of the mucous surface of the puerperal uterus remain localized. Reaction is such that the organisms are destroyed. If any escape into the blood stream they are so few in number as not to survive. The patient has an elevation of temperature for a few days, the lochia may be profuse and purulent for a time, but soon everything settles down to normal.

Extension by continuity of tissue results in a spreading inflammation of the mucosa, in an infiltration of the muscular wall of the uterus, or an extension to the tubes, with or without pus formation. If the lymph stream is invaded, a general peritonitis may occur, but more usually there results an inflammatory reaction in the cellular tissue of the broad ligaments with, in my experience, nearly always an involvement of the tubes—the so-called pelvic cellulitis. This may or may not go on to abscess formation, but nearly always remains localized to the pelvis.

Thrombus formation is always present at the placental site, and any organismal invasion of this area is peculiarly liable to cause an extension of it; hence the frequency of septic thrombo-phlebitis of the ovarian and other pelvic veins as a manifestation of puerperal sepsis. Bacterial invasion of the general blood stream I have already referred to.

These are the lesions our general knowledge of infections would lead us to expect, and these are the lesions which we find clinically and in the *post-mortem* room in cases of puerperal sepsis:

1. A localized surface infection of the mucosa.
2. Spreading infective lesion of the general surface of the mucosa, often with extension to the tubes.
3. Inflammatory infiltration of the uterine wall, sometimes with abscess formation.
4. Inflammatory effusion in the cellular tissue of the broad ligaments with or without pus, and usually accompanied by tubal inflammation with or without pus.
5. General peritonitis.
6. Septic thrombo-phlebitis of the pelvic veins with or without emboli, and with or without bacteraemia.
7. A general bacteraemia.

In any one case there may, of course, be a combination of these conditions. Knowing these to be the possibilities, how ought we to approach the investigation and treatment of the case of a woman confined two or three days previously and presenting febrile symptoms? The first thing to do obviously is to exclude the possibility of the fever being due to any other cause than puerperal sepsis. This involves a careful examination of the heart, lungs, kidneys, breasts, and other organs. Some time ago Dr. W. A. Scott and I made an analysis of all our cases of fever in the puerperium; in 2,096 cases confined in the Burnside Maternity Hospital, Toronto, 476 showed definite puerperal morbidity according to the standard laid down by the British Medical Association. In only 50 of these could we find any definite septic lesion in the pelvis. In 20 the cause of the temperature was extragenital from such conditions as pyelitis, cystitis, pneumonia,iliary tubercle, suppurating ear, etc. In the remaining 406 no definite lesion to account for the temperature could be detected by any of the ordinary methods of examination, including blood cultures. All of these patients made a

\* Read at meeting of Edinburgh Obstetrical Society, February, 1923.

perfect recovery without any treatment. What the cause of the temperature was we could not definitely say, but doubtless in a good many of the cases there was some infective lesion of a mild character somewhere in the genital tract.

#### TREATMENT.

The first thing to do in any case is, therefore, to make a general examination of the patient and to abstain from any local treatment until the indications for it are quite definite. Finding nothing extragenitally we should investigate the pelvic organs. The perineum is inspected. If there is a wound and it looks inflamed, any stitches ought to be removed and free drainage allowed. The same applies to stitches in the cervix. A careful and very gentle bimanual examination may now be made. At this early stage probably nothing will be discovered, or at most a large tender uterus with profuse and perhaps fetid lochia, but in the absence of physical signs in the other systems, or in the perineum or cervix, we conclude that the uterus is the source of the infection. Now at this stage I most emphatically hold that exploration should cease. There is a great temptation to try to find out what the condition of the interior of the uterus is by introducing the finger into it. As a matter of fact we are seldom much the wiser even if we do get the finger in, and the possibilities of doing harm are great. We presume that there is a localized patch of inflammation on the uterine mucosa. What good is it going to do to feel it? None whatever; and it may be productive of much harm by creating fresh raw surfaces and disturbing thrombi. For some days after delivery the placental site is raised and irregular owing to the normal thrombus formation in the vessels. Any rough manipulation of this area may readily convert a local into a general blood infection. And if this is possible as a result of a digital exploration it is still more likely to occur if a curette is used. When we find the source of infection in the perineum we do not use a curette to scarify the infected tissue. We do not use a sharp spoon for a recent infective ulcer anywhere else in the body. Why, then, should we do it in the uterus? There is no good reason for it and several very good ones against it. In the first place we cannot hope to curette the infected patch only and leave the rest of the mucosa untouched. We are bound to create a large number of fresh raw surfaces and inoculate into them the infecting germ, thus favouring local spread. We are bound to disturb thrombi and open up blood vessels, leaving the door open for a general infection. We remove the reaction zone of tissue, open up the lymphatic channels, and produce such a disturbance in the relation of parts by our manipulations that extension to the blood stream, to the broad ligaments and peritoneum, is favoured. We know that all these things are liable to occur. Does curetting the uterus favour them or not? I say most emphatically that it does. And yet we know that it is frequently carried out.

But I hear it asked, Suppose there is a piece of placenta or membrane left inside the uterus—may this not be the cause of the rise of temperature, and, if so, should we not get it out? There is no reason for thinking that a piece of membrane or of placenta retained in the uterus predisposes to bacterial invasion. A recent investigation of 149 cases of retained placenta showed that in 44 per cent. the puerperium was absolutely afebrile, in 50 per cent. there was very slight fever, and in only 6 per cent. was there severe fever, with one death, and in four of these severe cases there had been intra-uterine manipulation of various kinds. It has been my teaching for some time, in conformity with that of the great majority of obstetricians, that even at the time of confinement it is wrong to put the hand, finger, or instrument into the uterus to remove pieces of membrane or placenta which may have been left behind unless there is excessive haemorrhage. The risk of introducing septic organisms is far greater than that run by leaving things as they are. Such retained portions separate and come away of themselves in a few days. germ free uterine wall, how much more so is it when we know organisms to be present. The infective process is more likely to be in the part of the uterine wall from which the placenta has been detached rather than on that to which a small piece of membrane or placenta still adheres. In forcibly detaching such a piece we are not simply opening up fresh surfaces for infection. Therefore I hold that even when we know that there is a portion of placenta or membrane in the uterus it is wrong to curette or to introduce the finger or other instrument.

Even the intrauterine douche I believe to be more productive of harm than of good. The intrauterine douche was introduced as a means of treatment in the early days of antiseptics, when it was thought that they did much more in the way of destroying organisms in the tissues than we now know to be the case. Any antiseptic we may use as an intra-uterine douche has nothing more than a surface cleansing effect, and very little of that. It gets rid of possible accumulation of decomposing matter and pus from the uterine cavity, but the uterus is a muscular organ, and we have drugs at our disposal—ergot, pituitrin, and quinine—which, when administered, prevent any such accumulation. I can well remember when I was a house-surgeon in the Edinburgh Royal Maternity Hospital twenty years ago, when it was practically a routine to give an intrauterine douche to every patient with a rise of temperature lasting for more than two days, that in a very large proportion the douche was followed by a rigor or chill and a further elevation of temperature. That was supposed to be a nervous phenomenon. But was it? Is it not far more likely that it was due to a flooding of the blood stream with organisms—a temporary bacteraemia?

Sampson has shown, by injecting the venous channels of the uterus with a substance which gives a shadow with the x rays, what a very complicated system the veins form, and how free their communication is with the surface vessels of the mucosa. The thinness of their walls and the power of contraction in the uterine muscle makes it exceedingly easy for any minute substance in the uterine cavity or on the surface of the mucosa to be sucked into them, provided a surface vessel is laid open. Frank has shown, by blood cultures taken before and after intrauterine douching and simple manipulation of the uterus, that bacteraemia is very frequent after such proceedings. It is usually only a temporary condition, the blood again being sterile after a few hours, but if the initial dose of organisms is massive enough they may continue to grow and the case develop into one of true septicaemia.

Recent experience in the treatment of septic wounds has shown that the essential thing is free drainage, and the fewer antiseptics and the less interference the better. Now in the infected uterus the cervical canal always remains patulous and drainage is assured. It may be helped by placing the patient in the Fowler position and by administering the drugs I have mentioned. An ice-bag may be applied to the abdomen. It relieves any pain that may be present and reduces fever. A free liquid diet is given, the bowels are kept open but not severely purged, and if possible the patient is kept in the open air. Meantime a blood culture ought to be taken and repeated at intervals. We have ceased to take swabs from the interior of the uterus in the initial stages of infection because the results obtained were not commensurate with the difficulty of the proceeding and the risk to the patient. If there is accumulation of fetid discharges in the vagina a gentle vaginal douche may be given.

To this line of treatment the great majority of puerperal infections will yield and the patient make a perfect recovery. If extension takes place, this will declare itself in the course of a day or two and a definite diagnosis can be made. Cellulitis should be evident to bimanual palpation in three or four days; a pus tube a little later. When these have declared themselves the patient must make up her mind to a long period of inaction. In the majority of cases cellulitis will resolve in the course of a few weeks. A few undergo suppuration, and pus must be evacuated through the vagina or extraperitoneally through the abdominal wall. In the case of a pus tube we wait, if possible, until the temperature has reached and remained normal for some time before attempting removal. If the temperature remains high and the patient's general condition is deteriorating, pus may be evacuated through an incision in the posterior fornix and, if necessary, the tube removed at a later date. If there is evidence of peritonitis an incision may be made in the posterior fornix and drainage established.

Thrombo-phlebitis is evidenced by wide excursions of temperature, by repeated chills, and by the palpation of some thickening on one or on both sides of the uterus. Such cases may be dealt with by ligation of the ovarian or common iliac veins. This somewhat heroic treatment has been carried out by many operators, often with surprisingly good results. If there is evidence of local abscess formation in the uterine wall, hysterectomy can be performed. If the temperature remains high and there are not present in the pelvis physical signs to account for it the probability

is that there is a blood infection. This can only be shown by blood culture, frequently repeated if necessary. Dr. W. S. Cosbie, a member of my staff in Toronto General Hospital, took cultures from all puerperal patients running a temperature. His investigations are not completed, but we were surprised to find that so many of them had positive cultures at one time or other. Most of these made a complete recovery without special treatment.

In the treatment of true cases of bacteraemia we have used various kinds of intravenous medication such as magnesium sulphate, ensol, and salvarsan. We have also used serums. With all of them we have had recoveries, and at first attributed these to the drug used, until we found that, with no intravenous medication and with no serum, just as many patients got well. The great difficulty in assessing the value of these forms of treatment is that spontaneous recovery so often does take place.

What I have said regarding the treatment of puerperal infections occurring after a full-time delivery applies equally to those arising after abortion, either complete or incomplete. I make it a rule never to curette the uterus or carry out any intrauterine manipulation in a case of abortion if the patient has a rise of temperature, unless there is severe haemorrhage. If the abortion is incomplete and a mass is felt projecting through and blocking the cervical canal, this may be very gently removed, but more interference than that I think unwise. After the temperature has been normal for some days, if there is still evidence that the abortion is incomplete by the persistence of bleeding and the patulous condition of the cervix, gentle curetting may be carried out. Even after waiting this time it is almost invariably found that the patient's temperature rises after the operation, and she not infrequently has a rigor, showing almost certainly that there has been a blood invasion. Fortunately, in most cases, this is only temporary.

I have only touched very briefly on the whole subject of puerperal sepsis, but my purpose is served if I initiate some discussion on the inadvisability or otherwise of active interference with the interior of the uterus in the presence of fever. From all the evidence of the literature and from my own experience I hold that it is inadvisable.

## THE USE OF QUINIDINE IN AURICULAR FIBRILLATION.\*

BY

FRANCIS R. FRASER, M.D., F.R.C.P.Ed.,

DIRECTOR, MEDICAL PROFESSIONAL CLINIC, ST. BARTHOLOMEW'S HOSPITAL, LONDON.

THERE have now been recorded several hundreds of cases of auricular fibrillation in which normal rhythm has been restored, and it can be accepted as demonstrated that quinidine can bring about this change of mechanism in a large proportion of all cases.

Like all powerful drugs, quinidine can produce effects that are unpleasant, or even dangerous, and so it is necessary to learn in what cases the conversion can be effected without producing such results. The advantages to be gained might conceivably be so great that the risk of unpleasant symptoms would not be a serious deterrent to giving the drug, but in digitalis we have a method of treating the effects of auricular fibrillation that is so successful that it must be seriously considered in what cases a successful quinidine result surpasses in therapeutic value the effect of digitalis treatment.

Answers to the two following questions must be obtained before quinidine is to find a place in practical therapeutics:

(a) In what cases can the conversion be brought about without risk of producing dangerous symptoms?

(b) In what cases does the therapeutic effect of this conversion surpass the effect of digitalis treatment?

Discussion may well help to answer two further questions:

(c) What is the best method of administration in regard to dosage?

(d) For how long after the conversion should the quinidine treatment be continued?

Many other questions must arise, but preliminary answers to these four are desirable before the necessary amount of

evidence will be collected on which sound therapeutics can be based.

Among the earlier cases in which I tried quinidine was a woman, aged 54, with a greatly enlarged heart, severe mitral regurgitation, and stenosis of rheumatic origin, and auricular fibrillation. Quinidine sulphate (5 grains night and morning) caused auricular flutter to develop, and after eight days, during which the auricular rate was about 200 and the ventricular rate 80 to 90, the pulse rate rose suddenly to 200, probably as the result of a 1:1 response. On stopping the quinidine and commencing digitalis fibrillation returned.

A woman, aged 31, with mitral stenosis of rheumatic origin and severe heart failure, at rest in bed had a ventricular rate of only 50 to 65. After five days of quinidine sulphate (5 grains three times a day) auricular flutter resulted, and after six days more on  $7\frac{1}{2}$  grains three times a day she had a Stokes-Adams attack with ventricular standstill.

A woman, aged 54, with a greatly enlarged heart, mitral regurgitation, and auricular fibrillation, evidence of arterial and renal disease, and a ventricular rate of 180, responded moderately to digitalis. At a ventricular rate of 90 numerous ventricular extra-systoles occurred. With quinidine sulphate (15 grains at intervals of six hours) normal rhythm resulted after four doses, but was accompanied by precordial distress and nausea. On stopping the quinidine auricular fibrillation returned a day later with relief from the subjective distress.

Another limitation to the administration was seen in a woman, aged 48, with mitral stenosis of unknown origin and auricular fibrillation of probably only a few weeks' duration. The response to digitalis was good, but after nine days of quinidine sulphate, during which she received 175 grains in all, a severe toxic erythema developed with headache, nausea, and fever.

After the experience with these cases careful selection was made, avoiding all cases with evidence of much damage to the cardiac structures such as great enlargement, heart-block, or severe valvular disease.

A man, aged 39, with syphilitic aortitis and severe heart failure but no evidence of valvular disease, responded well to digitalis and received antisyphilitic treatment. Three months later normal rhythm was restored after ten days, during which 180 grains of quinidine sulphate was given. The treatment was continued for three months on diminishing doses, and nearly two years later the rhythm is still normal except for ventricular extra-systoles, and he feels fit to return to his work as a stevedore.

In the case of a man, aged 26, with no clear evidence of cardiac enlargement or of valvular disease and no evidence of infection other than malaria, a successful quinidine effect has continued for twenty months, and he is now working as a labourer. The auricular fibrillation had been present for six weeks before admission, and the digitalis response was good.

A similar successful result was seen in a man aged 40 with exophthalmic goitre, without evidence of valvular disease, in whom auricular fibrillation had been present probably for five years, and was still present three weeks after partial thyroidectomy by Mr. Dunhill. Normal rhythm resulted after four doses of quinidine sulphate (5 grains three times a day), and has persisted with gradually increasing efficiency for five months.

A woman, aged 45, with exophthalmic goitre of a mild degree had probably had auricular fibrillation for some years. Severe heart failure responded well to digitalis, and normal rhythm resulted after six doses of quinidine sulphate ( $7\frac{1}{2}$  grains three times a day). The dosage was gradually reduced and treatment discontinued four weeks later. An increase in the thyrotoxic symptoms was accompanied by a return of fibrillation. Partial thyroidectomy was performed by Mr. Dunhill, and as fibrillation was still present a week later quinidine was given, and normal rhythm returned after four doses of 5 grains three times a day.

Another case of this nature shows similar features.

A girl, aged 26, with mitral stenosis of rheumatic origin, responded well to digitalis objectively but continued to have severe dyspnoea and palpitations. Quinidine sulphate (5 grains three times a day) restored normal rhythm after seven doses, with relief from the palpitations. This dosage has been continued for nearly a year now, and a severe relapse occurred during a return of the rheumatic infection. Relapses of a few days' duration have occurred on three other occasions; on one she had a bad cold, on another much worry in connexion with the death of her mother, and on the third she tried to do some heavier work than usual.

There are cases of thyrotoxic auricular fibrillation in which normal rhythm was restored a few days after partial thyroidectomy without other interference, and cases in which auricular fibrillation occurred only for a few hours after operation during the stage of increased excitement. They suggest that the auricular fibrillation is due to an active toxic action, and that normal rhythm may result simply from the cessation of this action. The difficulty in obtaining a stable normal rhythm with quinidine in active toxic cases, and the stability obtained after thyroidectomy, indicate that in this type of case to obtain a stable normal rhythm the thyrotoxic factor must be treated.

In the other types of cases the indications of a similar active agent are not so complete, but the accumulation of more evidence may decide in favour of a similar state of

\* Abstract of remarks made in opening a discussion at a meeting of the Therapeutic Section of the Royal Society of Medicine, March 13th, 1923.

affairs in them also. The stability of the syphilitic case in which antisyphilitic treatment was given supports this view. The stability in the case in which no definite cardiac lesion could be found and in which the only known infection was malaria may well be due to the cessation of the causal factor, whatever it was, before the patient came under observation. The instability of the rheumatic case, even when quinidine treatment has been continued for nine months, is suggestive of a constantly or intermittently active factor tending to produce fibrillation. This idea is fully in keeping with the theory derived from the clinical study of such cases—that the rheumatic infection may continue for years, causing gradually increasing stenosis of the mitral valve, often without well defined attacks of acute rheumatic infection. In such a case it is of interest to note the additional factors present during the relapses into auricular fibrillation. Unfortunately there is no successful method of treating the rheumatic infection of the heart.

In addition to active agents it is probable that auricular fibrillation can result from permanent structural changes in the heart, in which case a stable normal rhythm after cessation of the quinidine administration would be unlikely.

#### CONCLUSIONS.

1. Quinidine treatment will result in a stable normal rhythm if the cause of the auricular fibrillation can be successfully treated or has ceased to be active.

2. Cases in which there are extensive structural changes in the heart are not suitable for quinidine treatment, especially if the response to digitalis is not good, as dangerous symptoms may result.

3. In some cases at least the comfort and efficiency of the patient is greater when a normal rhythm results from quinidine treatment than when digitalis treatment alone is used.

4. In the cases in which the results are satisfactory larger doses than 10 grains of quinidine sulphate at intervals of six hours were not necessary, nor smaller initial doses than 5 grains three times a day.

5. If necessary to maintain normal rhythm, quinidine may be continued to be administered indefinitely in doses of at least 5 grains three times a day, and it is probably advisable in all cases to continue it for some weeks after normal rhythm has resulted, though in gradually decreasing doses.

#### FIXATION OF CAECUM IN CHRONIC INTUSSUSCEPTION.

The following case of chronic intussusception which took an acute form came under my care in November of last year, and seems of sufficient interest to warrant publication.

N. C., a boy aged 4 years, was admitted to hospital on November 16th, 1922. The mother gave the following history:

On November 4th the child complained of severe pain in the region of the stomach. The pain was attributed to worms, and no significance was attached to it. The pain, however, recurred at varying intervals for the next few days. On November 7th the child vomited. The bowels had been quite regular, though once the mother noticed some "slime" in the stools. On November 11th the child was given two "yellow worm powders" and a large dose of castor oil. Two days later two round worms were passed. He still complained of pains, and cried almost incessantly until November 16th, when he was brought to hospital.

On admission his general condition was good. An indefinite tumour could be felt below the right costal margin, and there was loss of resistance in the right iliac fossa. He did not complain of pain. On November 17th and 18th the child had normal motions, but slight abdominal pain. On the 19th his stools were blood-streaked, the pain was worse, and a good deal of mucus was present in the motion. A typical sausage-shaped tumour could be felt in the region of the descending colon.

#### Operation.

The apex of the intussusception was in the left iliac fossa, about the beginning of the sigmoid, and was reduced with some difficulty. There was some extravasation of blood in the mesenteries of the small intestine and ascending colon, and the vessels were very much engorged.

An area about the size of half a crown at the apex of the caecum was grey and sodden. The appendix was healthy. The caecum and ascending colon were very mobile and the mesentery of the small intestine long. Owing to the congested state of the mesentery and ascending mesocolon I did not like to put stitches

in them, for fixation purposes, so I decided to use the appendix—(1) for fixation of the caecum, (2) by traction on it to turn the doubtful apex of the caecum up against the anterior abdominal wall, in case it should prove non-viable. I ligatured and divided the meso-appendix, and brought the appendix out through a stab wound just below McBurney's point, fixed it with a couple of sutures, and put a gauze wick down to the apex of the caecum, which was directly under the stab wound.

In forty-eight hours I removed the appendix level with the skin and withdrew the gauze drain; I also destroyed the mucous membrane with a probe dipped in pure carbolic.

The boy made a good recovery. The appendix required a second application of carbolic, as the mucous membrane was rather redundant, and secreted a little moisture.

A seven-hour picture after an umbroso meal showed the caecum in the position in which it was placed just below McBurney's point. It would be interesting to know—

1. In what percentage of cases there is recurrence of intussusception after operation.
2. If the risk of recurrence is enough to make an attempt at fixation worth while.
3. If fixation of the caecum by the appendix is suitable for prolapsed or mobile caecum, etc.

Londonderry.

#### SUBOCCIPITAL MENINGOCELE SUCCESSFULLY REMOVED.

The following case, in which a large meningocele which was present at birth was successfully removed by operation, is, we think, of sufficient interest to warrant publication.

Marie P. was born on May 19th, 1921, with a large meningocele, the birth being uneventful and taking place before the arrival of a doctor. The baby was otherwise healthy. It was found that the growth steadily increased after birth, and the covering becoming thinner, it was obvious that rupture was imminent. It was decided to operate, and the baby was removed to North Londonderry Hospital. Before operation the dimensions were: horizontal 6½ in., vertical 5 in., circumference at junction with skull 7 in.

#### Operation.

On August 1st, 1921, assisted by Dr. T. E. Roberts, I dissected back the skin and exposed the underlying membrane. This was very difficult near the neck of the sac, as there was practically nothing between skin and membrane. With a large opening

Photographs showing the child before and after removal of the meningocele.

between sac and the skull there was danger of collapse from sudden loss of cerebro-spinal fluid; to obviate this an intestinal clamp was loosely applied to the neck of the sac. The sac was then opened at a distance to verify the absence of nerve tissue. The clamp was quickly closed, thus preventing leakage of fluid. The sac was cut away and a continuous suture applied round stump and clamp, as in Barling's operation for piles. The clamp was withdrawn and suture quickly tightened. A few interrupted sutures were applied where fluid was oozing. The deeper structures were drawn over the stump and the wound closed. An anchor dressing was applied.

For a few days the temperature oscillated between normal and 102°, with muscular twitchings suggestive of impending convulsions. Bromides were given, and the temperature came down to normal and all twitchings ceased. Owing to fear of yielding of scar the anchor dressing was kept on for two weeks and cut its way out, leaving a granulating surface which did not involve deeper structures. Secondary suturing closed this, and complete healing quickly followed. The baby was sent home well five weeks later, and has remained well and normal since. She has just recovered from whooping-cough and is beginning to walk.

I am indebted to Dr. Kathleen Rutherford for the photographs, which show the baby before and after operation, also for her very helpful interest in the case. The ultimate recovery of the baby was largely due to the skilful nursing of Sister Levison.

## Reports of Societies.

### THE NEED FOR PUBLIC EDUCATION IN THE CONTROL OF CANCER.

A MEETING of the Fellows of the Royal Society of Medicine was held on March 13th to discuss the urgent need for education in the control of cancer. The President of the Society (Sir W. HALE-WHITE) was in the chair.

Mr. J. E. ADAMS, who introduced the subject in a brief address, said that his own desire had been to see the formation of a society for the control of cancer, similar to the societies already in existence for combating tuberculosis and venereal disease. But before anything of this kind could be done the support of the profession had to be enlisted, and as he thought that the Royal Society of Medicine—without any disrespect to other bodies—was the headquarters of scientific intelligence in the medical profession, it was proper that the first meeting on the subject should be a meeting of the Fellows. It was well known that cancer was on the increase. Little more was known as to its causation than was the case twenty years ago. The majority of cancer patients came for medical assistance too late for any reasonable chance of cure. Medical men were all aware of a number of conditions which predisposed to cancer, such as syphilis, chronic degenerative mastitis, and unhealed ulcerations of the uterine cervix. Were these conditions treated as energetically as their association with cancer demanded? In any woman over 40 a lump in the breast was ten times more likely to be malignant than to be simple. Middle-aged men were apt to think that indigestion and haemorrhoids were the inevitable result of a sedentary life, and that a bottle of medicine or a few pills would put them right; but the real trouble might be a growth in the bowel. It ought to be recognized by the public that treatment without examination was not worth paying for, and by the profession that it was not worth doing. The public required enlightenment on this matter. He proceeded to give details of the intensive campaigns carried out by the American Society for the Control of Cancer, which was founded in 1913 in New York to disseminate knowledge concerning the symptoms, diagnosis, treatment, and prevention of the disease; to investigate conditions under which cancer was found; and to compile statistics in relation thereto. Pamphlets which the man in the street could understand were issued by this body, and publicity was further assured by posters, films, and public meetings. He was informed that there had been no serious trouble from cancerophobia as a result of this agitation. In this country little had been done, though the medical officers of health for two or three local authorities—notably Portsmouth, and Holborn in London—had spread leaflets broadcast urging people who had certain symptoms to consult a doctor without delay. He gathered that the British Red Cross Society was prepared to help in the distribution of authoritative intelligence, compiled by medical men, on this subject, and he suggested that a committee might be formed by the Council of the Royal Society of Medicine to collect and transmit the facts to the Red Cross Society. To avoid the danger of oblique advertising, nothing should be published except under the imprimatur of the committee, and all names save that of the Royal Society of Medicine should be withheld. He proposed the following resolutions:

That it is desirable that the public should be given more information as to the early signs of cancer and the prospects of cure by immediate treatment.

That the British Red Cross Society be asked to conduct this publicity campaign by means of lectures and pamphlets.

That the Council of the Royal Society of Medicine be requested to nominate a standing committee to supply information to the British Red Cross Society suitable for wide dissemination and the education of the public.

Dr. LAPHORN SMITH seconded the resolutions. He believed that the propaganda should start with the medical profession, and be extended to nurses, midwives, clergymen, district and health visitors, and all who came in touch with the homes of the people.

Mr. C. P. CHURCH (President-elect of the British Medical Association) said that seventeen years ago he contributed a volume to the New Library of Medicine advocating the course which it was now proposed to adopt. He believed that that book, *The Control of a Scourge*, which was also published in America, might have had something to do with the growth of the idea which resulted in the American Society for the Control of Cancer. He was told by the

publishers that lately there had been an increased demand for the book in this country, and he was asked to prepare a second edition or to rewrite the book. The most important step was to secure the support of the medical profession. The cause of cancer was not yet known, but things which were known were its age incidence, its frequent association with chronic irritation, and that it was in the first instance a local disease and later disseminated itself widely from its point of origin. The clinical descriptions of cancer in the textbooks were not those of early cancer at all. The fact to be grasped was that cancer was a curable disease, and yet very few cases were cured. The disease being curable, it was the duty of the medical profession to put the public in a position to profit from the possibility of cure. The only possible objection was cancerophobia, but he attached very little weight to that. The public knew already what a deadly disease it was, and he did not think that cancerophobia would be more frequent than now if people were told simply that by applying earlier for treatment they might possibly be cured. All women should be told, for instance, that if bleeding persisted after the menopause they should consult their doctor at once. The same course should be taken in the case of men advancing in life who had any sore on the lower lip. He pointed out the need for the instruction of nurses and midwives as a part of their curriculum in the importance of noticing early signs of cancer and bringing such cases to medical attention.

The Hon. Sir ARTHUR STANLEY (Chairman of the British Red Cross Society) said that his society would be glad to do anything it could to help in this work. The society was not merely a war society. Its workers were anxious to carry on the Red Cross tradition into peace. But in all that it could do in the way of publicity it understood thoroughly the need for close medical supervision.

Lord DAWSON of PENN said that the fact must not be lost sight of that research into the causes of cancer must always stand in the forefront of the programme. But while they were waiting for the much desired results of that research it was necessary to get existing cases under treatment as early as possible. The first thing to do was to bring home to the profession the need for a closer appreciation of the early symptoms of the disease. He believed that attention was paid to this matter in the medical schools at the present time. But when the qualified man went out to take up his practice he found himself deprived alike of the atmosphere and the equipment to which he had been accustomed in hospital. He was deprived in many instances of those ancillary means of diagnosis which were of such great value, and the effect of that was not only to limit his powers but slowly to discourage his zeal. Until hospital and clinical equipment was made readily accessible all over the country the movement in this respect would be handicapped. If medical men were given proper opportunities and were encouraged to take the utmost care in this matter it would have a repercussion upon the public, for good doctors always meant sensible patients. He was doubtful of the value of a direct and specialized propaganda against cancer. The more useful plan was to educate the public in health by means of lectures which dealt with health and variations from health, and incidentally the signs of such variations, not of cancer only but of every disorder, and to avoid the special application of a symptom to a particular disease. This last was the function of the doctor. The significance of the variation should be left to the doctor, whom the patients should be encouraged to consult. He thought cancerophobia a real danger, but that by these means it could be averted. In propaganda it was not enough to be intensive and energetic; one must also be wise. Lectures were the most appropriate means for educating the public. To employ broadcasting and cinemas would mean the concentration of attention on morbid and lurid aspects, which would do more harm than good. The antiveneal campaign began under very special circumstances, and no doubt its methods of propaganda at the time were rightly chosen. But even there the time had now come to transfer the propaganda from the streets to the lecture hall, where, in the case of cancer, it ought to begin.

Dr. HERNERT SPENCER said that sixteen years ago he read a paper at the Annual Meeting of the British Medical Association at Exeter dealing with measures to be recommended to secure the earlier recognition of uterine cancer. The views expressed in that paper were received with a unanimity rare in professional discussions, especially gynaecological ones.

One line of action which he advocated was to bring forward for demonstration to the students in the medical schools patients who had remained for twenty or twenty-five years free from recurrence. This would effectively counteract the pessimism which existed in the public mind, and to some extent in the professional mind, with regard to the possibility of cancer cure. Even the smallest town ought also to have its cottage hospital where visiting consultants would be available to examine patients referred for suspected cancer.

Sir NAPIER BURNETT urged that the out-patient departments of hospitals, instead of being in charge of the junior members of the staff, should be visited by the senior members, for here they would be able to do much in the early detection of cancer, whereas in the wards they saw chiefly the advanced stages of the disease.

Mr. CECIL ROWNTREE pleaded for more intensive and highly organized research work into the cause of cancer and a better distribution of clinical and pathological material among the different laboratories so as to prevent duplication of researches. A central body to guide the work done in the different laboratories so that it might have more cohesion and sequence seemed desirable, as well as some method of pooling and periodically publishing the progress of experiments.

Dr. MEARNS FRASER (M.O.H. Portsmouth) said that cancer was rapidly obtaining the most prominent position in the death returns. Twenty years ago in Portsmouth it accounted for one death in twenty, now it accounted for one in ten. Thousands of people were losing their lives yearly who might have been cured had they consulted their doctors at an early stage. He urged that the proper people to bring the matter forward were the local health authorities.

Dr. S. MONCKTON COPEMAN (Ministry of Health) said that the Ministry had recently founded a departmental committee on cancer, to which it was proposed to co-opt representatives of various bodies who were interested in the subject from the clinical and pathological sides. He suggested that the Royal Society of Medicine might perhaps think it desirable to co-operate with the Government committee before taking any special line of its own. The Public Health Services of the State, including the nurses and health visitors, could all be made use of for this purpose.

Dr. JOHN SHAW urged that the statistical returns proved the uselessness of operations for cancer. The evolution of the modern operation for cancer of the female breast, its greater frequency, its earlier date, its wider extent, had resulted in a progressive increase in the death rate and the curtailment of the span of life of its victims, notwithstanding diminished immediate risks from operation. Fresh surgical "triumphs" had been attended by rapid rises in the death rates from cancer of the organs concerned.

The resolutions were then put and carried.

## RADIUM TREATMENT OF UTERINE HAEMORRHAGE.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, held on March 1st, with the President, Dr. T. WATTS EDEN, in the chair, Mr. SIDNEY FORSDIKE read a paper on the treatment of severe and persistent uterine haemorrhage by radium, with a report upon 45 cases.

Mr. Forsdike dealt with the type of case which was sometimes described as the bleeding uterus, where no pelvic lesion could be found to account for the haemorrhage, and the cases cited were those which had proven refractory to palliative and to operative treatment. Of the 45 cases under consideration no fewer than 26 had undergone some form of operation or combination of operations, including dilatation and curettage, removal of polypi, amputation of cervix, oophorectomy, or salpingo-oophorectomy, and some of the cases had been curetted more than once. Four of the cases were associated with fibroids. All the uteri were enlarged, but were broadly divisible into two groups: (a) the systolic uterus, which admitted a sound for 3 to 3½ inches, and which yielded little or no tissue to the curette; (b) the diastolic uterus, which admitted a sound for 3½ to 5 inches and which yielded an amount of thickened endometrium. In all cases an exploratory dilatation and curettage was done and any tissue removed was submitted to microscopic examination. The cervix, if unhealthy, was submitted to a preliminary

cleansing treatment. The radium was placed *in utero* and only the gamma ray used. The vagina was plugged, with the twofold object of maintaining the radium in place and of keeping the bladder and rectum away from the source of energy. The additional precaution was taken of introducing a self-retaining catheter into the bladder for twenty-four hours. There were two main groups of cases: (a) those in whom it was desired to modify the catamenia by exposure to small doses of radium, of which there were 3 cases; (b) those in whom it was desired to suppress entirely that function by exposure to a heavy dose of radium, of which there were 42 cases. In group (a) two of the three cases were successful, and the third had an ovary removed at another hospital after an initial treatment. In group (b) all the cases responded to treatment, five of them requiring a second exposure. Generally speaking, no anaesthetic was required in giving a second exposure. In a certain number of cases some pain and discomfort were noted while the radium was *in situ*, which disappeared promptly on the removal of the radium. In a few cases post-anaesthetic vomiting was aggravated, but quickly subsided upon withdrawal of the tube. As regards the results of treatment, in 10 cases there was no further haemorrhage, in 17 cases there was one period, in 11 cases there were two periods, and in 4 cases there were three periods, the actual quantity of blood lost being small; but in cases where the exposure was given immediately before a period was due the loss was apt to be severe. The radium menopause was due entirely, he believed, to action upon the uterus, in favour of which the evidence rested not only upon clinical but on experimental grounds. Radium was implanted in the uterus of a cat, and the opposite ovary was fixed at a distance of 8 cm. from it; the results were noted at the end of twelve, twenty-one, and sixty days. In none of the experiments did the ovary show any macroscopic or microscopic change, whereas the irradiated endometrium showed a gradual transformation into connective tissue, with an entire loss of glands, suppression of blood vessels, and a notable diminution in the number of stroma cells. There was one absolute contraindication to the use of radium in these cases, and that was the presence of a pelvic inflammation, recent or remote, as it was likely to set up abscess formation.

Dr. BLACKER said he had been treating haemorrhage from the uterus at the menopause, in small fibroids, and in cases of so-called functional menorrhagia, since 1916. He had had altogether 77 cases, and his results had been uniformly good. Radium was a specific for climacteric haemorrhage. It should only be employed in small cases, and in the absence of any pelvic complication, such as disease of the appendages, was a complete bar to the use of radium. The chief action of radium was, he believed, on the ovaries.

Mr. PROVIS thought that x-rays were just as successful as radium, if not more so, in cases of menopausal haemorrhage.

Professor HENRY BRIGGS showed a specimen of angioma of the vaginal wall, found in a primigravida at the thirty-sixth week of pregnancy; there was no history of local injury and no unusual varicosity of vulval or other veins. Mr. A. C. PALMER showed a mass of secondary leiomyosarcoma which originated in the stump of the cervix after subtotal hysterectomy. Mr. EARDLEY HOLLAND showed a leiomyosarcoma of a fibromyoma removed by subtotal hysterectomy; examination revealed cystic degeneration of a fibromyoma which had undergone sarcomatous changes. Dr. J. D. BARNES showed two specimens of sarcoma of the uterus. The first was obtained *post mortem* from a multipara aged 57. The second was obtained by panhysterectomy from a multipara aged 67, who had had profuse vaginal haemorrhage for three weeks. Recurrence took place two months after the operation, and she died in three months from haemorrhage from secondary vaginal masses. The uterus was filled with a large friable growth. Dr. RUSSELL ANDREWS said that in his own experience of sarcoma of the uterus the growth usually recurred within a short time of operation. Dr. BLACKER thought that in any case in which subtotal hysterectomy was practised the tumour should be opened before the operation was completed, and that if the tumour showed signs of breaking down, other than simple cystic degeneration, the cervix should be removed. Mr. LUKER showed a specimen of chorion-epithelioma of the uterus; the chief symptom was abdominal pain, with anaemia, rhoea for the last three months; the uterus was enlarged, forming a tumour reaching almost up to the umbilicus, and death occurred from haemorrhage from perforation of the right vaginal fornix by the growth.

## THE TREATMENT OF PUERPERAL INFECTIONS.

At a meeting of the Edinburgh Obstetrical Society on February 14th, when the President, Dr. J. LAMOND LACKIE, was in the chair, Professor B. P. WATSON read a paper on the treatment of puerperal infections, which is published in full at page 505.

Dr. HAIG FERGUSON thought Professor Watson had expressed views very generally held, and had brought out very clearly the points which now influenced local treatment of a septic uterus. There could be no question as regards the inadvisability of using the curette, but he thought Professor Watson had been rather severe upon the intrauterine douche. To get the best results from the intrauterine douche it should, of course, be used early, before the poison was absorbed into the system. He did not think that its early use was in any way contraindicated, provided care was taken not to introduce any fresh organisms into the uterus from the vagina, or to use too strong an antiseptic, and that the temperature of the douche was from 115° to 120° F. The stimulation of the hot water undoubtedly helped to intensify the use of drugs like pituitrin, ergotin, and quinine. He used an emulsion of turpentine, the value of which was first brought to his notice by Fabre de Lyons. The emulsion could easily be made by mixing a teaspoonful of turpentine and a teaspoonful of lysol in each pint of water. The turpentine loosened any shreds of dead tissue which might be adherent in the uterus, and was a very safe antiseptic.

Dr. KEEPLE PATERSON mentioned two cases which occurred when much less was known about antiseptics and when instruments were not boiled but soaked in an antiseptic lotion. The forceps were the evident source of the sepsis in both; in one the temperature rose about the seventh day to 103.4°; it fell within a day to normal and remained so after one intrauterine douche of 1 in 2,000 sublimate lotion, which was the antiseptic then mainly used. In about a week another case showed a temperature of 106.6°, which became normal within twenty-four hours after one intrauterine douche, and though there was a slight rise subsequently the temperature very soon fell permanently to normal. In surgery the first principle in treating sepsis was to remove the focus if possible. It was not safe to trust to the patient's blood, it might not be in a healthy condition. He had never seen rigors nor any bad results after intrauterine douching, and believed that they were due to faulty technique by grazing the uterus in the insertion of the catheter and so creating a fresh surface for septic absorption. So the parturient canal after labour was often in a more or less lacerated condition and liable to contamination both from within and without. He practised thorough irrigation with sublimate lotion (1 in 4,000) once immediately after labour in practically every case with excellent results.

Dr. FORDYCE was in cordial agreement with almost all that Professor Watson had said. He was surprised that Professor Watson had found it necessary to emphasize the importance of not curetting the uterus in septic cases. He had long ceased to explore the uterus for a piece of membrane. He had also given up the intrauterine douche, except in cases where the infection seemed to start very early—at about the third day—when an intrauterine douche might be indicated. In fact, when a patient had puerperal fever, her recovery depended upon her own powers of resistance and her own strength. In cases of abortion, if the patient had high fever, and not very much haemorrhage, he thought it advisable to dilate the cervix, explore with the finger, and remove the putrid placental tissue. It seemed that the poison must be of local manufacture, and to leave it would be very dangerous. It was true that after the removal of the placenta a rise of temperature might occur, but in the great majority of cases it was only temporary and the patient made a complete recovery afterwards, while if it were left the patient would go on absorbing more and more poison and would probably die. Dr. Fordyce thought it would be exceedingly dangerous to stand by and do nothing.

Miss BENZEL expressed herself as entirely in agreement with what Professor Watson had said, especially with reference to the treatment of septic abortion. She quoted one case in which curettage was followed by development of pelvic cellulitis. Dr. YOUNG wondered whether Professor Watson's routine was quite in conformity with general surgical principles, because he seemed to base his whole routine on the analogy with the procedure carried out in ordinary surgical sepsis. If the uterus contained a piece of dead tissue was it the proper course to leave it there and

rely upon the uterine contractions to expel it? Dr. JOAN ROSE suggested that the same kind of treatment should be given to retained portions of membrane and placenta as to cases of adherent placenta—namely, manual removal at labour. She cited a case where non-removal of retained products of conception had been followed by chorion-epithelioma as well as sepsis. Dr. H. S. DAVIDSON said that the strongest point for Professor Watson's method was that the death rate for puerperal fever had not come down within the last few years. It took a pretty strong mind, however, to adopt an entirely watching attitude, and Dr. Davidson had stuck to the use of pure carbolic, followed by a mild douche. Dr. FRASER LEE suggested that where something was left in the uterus after either an abortion or a confinement it ought to be removed. He never curetted in these cases, but, if there was any suspicion of pieces of placenta being left behind, he always put a hand into the uterus after the confinement. He agreed with Dr. Fordyce as to abortions, and never trusted either the patient or the relatives, who so often insisted that everything had come away. He explored the uterus under an anaesthetic and quite often found pieces of tissue left behind. He used a blunt curette and gave an intrauterine douche and had seen no rise of temperature or sepsis in these cases.

The President remarked that one of the difficulties in treating puerperal sepsis was that of early diagnosis. Intrauterine douching, if used at the commencement of the illness, was of great value, and the application of pure carbolic acid a useful adjunct. Douching used a week or ten days after confinement was of no avail. He entirely agreed with what had been said about curetting in puerperal sepsis. If at the time of confinement it was recognized that a large piece of placenta had been left behind it was justifiable to remove it at once, but if there were only a small piece or some shreds of membrane it was far better to leave them alone. The rigor which occurred after intrauterine douching no doubt indicated bacteraemia, but it did not seem to do much harm, as the temperature as a rule fell rapidly to normal and continued there. In septic abortion he thought that as much as possible should be removed, without, of course, the use of any sharp instrument. At present he was inclined to continue local treatment in these septic cases, but no doubt the day might come when they would be more satisfactorily treated by vaccines or serums.

Professor WATSON, in reply, said that the ideas he had put forward as to the intrauterine douche were based on actual experience in the hospital with which he had been connected in Toronto, where all forms of sepsis had to be taken in. Almost invariably he had found that when a patient was admitted with puerperal sepsis there was a history of interference with the uterus—possibly it had been curetted during the febrile period. With the intrauterine douche there was a risk of carrying more into the uterus than could ever be got out of it. He considered that as used in private practice the douche was a great source of danger. In a case of abortion, if it were incomplete and the patient had no rise of temperature, the material should be immediately cleared out, but if the temperature rose it was necessary to wait until it fell before clearing out the remains. If in the meantime death occurred it was due to bacteraemia, which would have been aggravated by interference.

## PLASTIC REPAIR OF THE FACE AND LIMBS.

At a meeting of the Edinburgh Medico-Chirurgical Society held on March 7th, with the President, Sir R. W. PHILIP, in the chair, Mr. J. J. M. SHAW read a communication upon the plastic repair of the face and limbs, and exhibited a series of lantern slides which illustrated the practice and results of two methods employed—the Thiersch graft upon a mould and the tube pedicle.

After paying a tribute to the influence of Mr. H. D. Gillies in the recent developments in plastic surgery, and to the value of an association with him at Queen's Hospital, Sidcup, Mr. Shaw described the method of applying the Thiersch graft wrapped around the dental composition known as "stent," and showed photographs of illustrative cases indicating its usefulness in ectropion of the eyelids, in adhesions of the labio gingival sulcus which prevent the fitting of dentures, and as an intra-nasal lining in deformities caused by lupus, syphilis, and old-standing trauma. Reference was made to the necessity of supplying, in these types of nasal deformity, a new cartilaginous framework, angled at the tip of the nose and supported both at the glabellar region and at the spine of the

maxilla, in addition to the restoration of the lining. In all cases a temporary improvement could be effected by the insertion of a simple straight slip of cartilage, but it was only in a condition of comparatively recent trauma, in which no intranasal lesion of an ulcerative type had existed, that a permanently satisfactory result could be attained by a cartilage which was supported by bone at the upper end only.

The two varieties of tube pedicle grafts, to which were applied the distinguishing names of anastomotic and arterial, were next demonstrated. In the former, most commonly fashioned upon the neck or abdomen, three operative stages were required. The skin tube was first prepared, both ends being left untouched. By daily constriction of the end which was first to be freed, the anastomotic channels of the other end were developed. Three weeks later the pedicle was divided at the end prepared for separation, partially opened out and implanted at a suitable margin of the new bed. After the lapse of another three weeks the remaining original attachment was set free and the pedicle opened throughout its whole length to fill the defect completely. The length and flexibility of the pedicle obviated the need for firm fixation of the parts in the intermediate stage. In the arterial type the operation was carried out in two stages. The most common example was the forehead flap, in which the pedicle contained the anterior branch of the superficial temporal artery. Owing to its dependable viability, the implantation of the freed end on to the face could be effected at once, and a fortnight later the second stage was carried out by the return to the forehead of the proximal part of the pedicle which had served as a conduit. The gap on the forehead, corresponding to the portion of skin which was now implanted on the face, was covered by a whole-thickness skin graft from the abdomen or by local advancements of the scalp. Examples were shown of the treatment by the forehead flap of facial disfigurement due to burns, port-wine stains unsuccessfully dealt with by other means, lupus excision, and gunshot wounds. In chronic ulceration and cicatricial contractures of the arms and hands, the employment of the abdominal anastomotic pedicle was illustrated. In these situations the tube pedicle was considered to be the most effective method of plastic repair. For the lower limbs, the pedicle graft, whether obtained from the sound limb or from the abdomen by successful "caterpillar" stages, was not advocated until it became evident that healing could not be effected by splintage and rest nor by free grafting.

The communication was discussed by Sir HAROLD STILES, Mr. GUTHRIE, Mr. WADE, Mr. STEWART, and Mr. PIRIE WATSON; and Mr. SHAW replied.

#### Clinical Cases.

Sir DAVID WALLACE showed (1) a case of exophthalmic goitre operated on thirteen months previously. The case had been treated medically for over a year prior to operation without benefit. The operation had been completely successful in relieving symptoms. (2) A case of epithelioma of the tongue in which no recurrence had followed resection of one-half of the tongue two and a half years previously. Dr. DAVIES reported a case of tetany following removal of the right lobe of the thyroid gland; the left lobe had been removed two years previously. The condition was benefited from large doses of calcium lactate and subcutaneous injection of parathyroid in 1/10-grain doses. Dr. PATERSON showed a case of pulsating exophthalmos from a non-traumatic arterio-venous aneurysm of the cavernous sinus and internal carotid artery. Dr. GOODALL showed a case of severe arthritis deformans, in which benefit had followed weekly intramuscular injections of peptone in 0.2-gram doses.

### MENTALLY DEFECTIVE CHILDREN.

A MEETING of the Ulster Medical Society was held in the Medical Institute, Belfast, on March 8th, with Professor JOHN W. President, in the chair.

Dr. DAWSON, chief medical officer of the Government of Northern Ireland, read a paper on the care and education of mentally defective children. He dealt fully at first with the classification and general pathology. An idiot was unable to guard himself against danger and had a mental equipment not exceeding that of a child of 2 years of age. An imbecile could guard himself against danger but could not earn a livelihood; his mental age lay between 2 and 7. The feeble-minded were permanently incapable of benefiting by education, and there were various subdivisions of this latter

division. Dr. Dawson then gave a description of the Darent Training Colony with its list of occupations, training, classes, and system of education generally. He remarked that it was generally asserted that these children would require life-long control, and so such expenditure was a waste of money; but some did remarkably well, many were greatly improved and were able to help in home work; all these would inevitably drift into public institutions, prisons, workhouses, penitentiaries, asylums, and so would have ultimately to be supported by public money. These homes and training schools minimized the evil; those cases that merely develop late were rescued, vicious tendencies and faulty habits were suppressed, and a certain amount of education, especially manual, was imparted; the children were taught to play, learn some one trade well, and solitariness was avoided. In Scotland the boarding-out system was common under strict supervision; it gave the child a home life and was economical.

Dr. LEE read a paper on the treatment of congenital syphilis, which was based on the results of 20 cases treated in the Children's Hospital. He referred to a large number of the moot points in congenital syphilis, and explained the method of administering the later preparations of salvarsan to infants.

The PRESIDENT raised the question whether sterilization by x-rays had been practised. Dr. CALWELL referred to the cause of feeble-mindedness; it was not altogether due to alcohol, nor to syphilis, nor yet to heredity, although the latter was the strongest factor. He thought it a pity that the Binet-Simon tests and their modifications were not more commonly and systematically used. The evil was clear; and, as shown by the paper, the remedy was also clear, but the difficulty was finance. He thought an institution was an absolute necessity, but general hospitals should open a mental out-patient department, where all such cases could be seen.

Dr. HOUSTON did not accept all the conclusions of Dr. LEE as regards the syphilitic problems; he asked how far hereditary syphilis was a cause of congenital mental defect. Mr. FULLERTON raised the question of the surgical cure of hydrocephalus by opening the Sylvian duct and otherwise restoring the free circulation of the cerebro-spinal fluid. Professor MACLEWINE said the evening had shown the necessity and advantage of linking up experimental and practical therapeutics. Dr. TRIMBLE said that an intelligent basis of education was necessary, not only in dealing with these children, but in all schools. Dr. DAWSON and Dr. LEE replied.

### CAUSE OF DEATH IN INTESTINAL OBSTRUCTION.

A MEETING of the Surgical Section of the Royal Academy of Medicine in Ireland was held on March 9th, with the President, Sir WILLIAM I. DE COURCY WHEELER, in the chair, when Mr. SETON PRINGLE read a communication on the cause of death in intestinal obstruction.

Mr. Seton Pringle, having briefly reviewed the three theories that had been advanced on this question—namely, (1) infection, (2) absorption of toxins from the obstructed intestine, and (3) depletion of the system in circulation and cerebral anaemia—went very fully into the experimental work that had been done by workers in the British Isles, America, and the Continent. From this work two facts confirming clinical experience stood out pre-eminently—peritonitis was not the chief factor in causing death, and the higher up the obstruction the more rapidly was it fatal. In addition he drew the following conclusions: (1) The principal factor in causing death in intestinal obstruction was a toxin which was developed chiefly in the duodenum, and, although not absorbed from normal intestine, was absorbed under the conditions which prevailed in obstruction. (2) The exact chemical composition of the toxin was still under dispute, but it was almost certainly of the nature of one or other of the toxic bodies derived from protein disintegration. (3) The exact mode of production of the toxin was also undecided, but probably the presence of pancreatic secretion, and, in a lesser degree, the activities of bacteria were necessary for its production. (4) While the duodenum was the site of maximum toxicity in obstruction, yet the poisonous substances were developed lower down in the intestine, and it was probable that in the production of these toxins bacterial action played an important part—a part which increased in importance the lower down the obstruction occurred. Mr. Pringle believed that those conclusions for the most

part held true when examined under the searchlight of clinical experience, although at the same time he considered that toxæmia was rarely the only factor in causing death, and that shock was one which played a more important part than the literature would lead them to believe. He suggested that intestinal toxæmia had a large share in causing death in acute septic peritonitis, together with the factors of shock and septic absorption from the peritoneum. Arguing that if the shock were combated there was a possibility of prolonging the patient's life sufficiently to enable the fighting powers of the peritoneum to deal with the infection, he urged not only the use of morphine and saline-glucose infusions to cope with the shock and toxæmia, but also strongly advocated a direct attack on the sources of the toxin by means of an enterostomy high up in the small intestine, after the manner of a Witzel's gastrostomy. The technique of the operation was described in detail, and Mr. Pringle said that most encouraging results had been obtained by adopting this line of treatment in such cases.

Mr. W. DOOLIN thought that the toxæmic factor was the main one. He had never seen a case in which the patient died of shock within twenty-four or forty-eight hours; in fact, in the cases he had seen it had seemed extraordinary the length of time the patient lived in spite of the intestinal obstruction. Mr. HENRY STOKES was of opinion that primary shock was rarely responsible for death in intestinal obstruction. He thought that shock was brought on more or less gradually, by toxins and loss of blood, and in such a case there would be no dilatation of the vessels. Mr. ADAMS MCCONNELL also spoke. The PRESIDENT expressed the opinion that in cases of intestinal obstruction a patient's power of getting rid of toxins was increased, and the stomach became an excretory organ. In these cases lavage of the stomach should be carried out every two hours. Frequently such cases were treated by giving pituitary extract and enemas, but he thought that there came a stage when that treatment was wrong, and when enemas should be stopped, morphine given, and the stomach frequently washed out. If morphine was given for two days or so the patient's bowels began to act, diarrhoea often set in, and thus toxins were got rid of. That bore out how much shock had to do with these cases. He was of opinion that stimulants were contraindicated, and that sometimes in acute cases, unless morphine was given, the patient would die.

Mr. W. C. STEVENSON then read a report on 132 patients treated with radium emanations during 1922, and showed two male patients who had been treated with radium emanations during 1922. The PRESIDENT showed a specimen of a renal squamous-celled epithelioma from a patient who had four stones in the kidney. In the published cases of primary cancer in the kidney a considerable percentage had stones in the kidney, which looked as if stone was an important factor in the production of cancer in the kidney.

### HEART-BLOCK.

At a meeting of the Manchester Medical Society held on March 7th, with Sir WILLIAM MILLIGAN in the chair, Dr. J. C. BRAMWELL read a paper on some aspects of heart-block. He said the introduction of the electro-cardiographic method had thrown much light on the mechanism of the heart beat and the disorders to which that mechanism was subject in disease. Some of the more recent work in particular had an important practical application to the clinical problem of prognosis. In its mildest form heart-block was characterized by a prolongation of the interval which elapsed between the contraction of the auricle and ventricle. It differed therefore only in degree from the normal mechanism, which served to prevent simultaneous contraction of these two chambers, such as occurred in some cases of "nodal rhythm." In addition to the more familiar forms of partial and complete block, lesions of one or other of the main branches of the a-v bundle gave rise to characteristic alterations in the ventricular complex of the electro-cardiogram. This was because the excitation wave was forced to pursue an abnormal course and was delayed in its passage to the affected ventricle. In certain cases of grave myocardial disease a form of electro-cardiogram was met with which resembled that of branch bundle lesions in the increased duration of the initial ventricular deflections, but differed from the latter in its smaller amplitude and in a peculiar notching of the O.R.S. group. Rothschild and Oppenheimer considered this type of electro-cardiogram characteristic of a lesion affecting the terminal arborizations of the Purkinje system. Whether this hypothesis would ultimately prove to be correct was un-

certain, but the records of this type were undoubtedly of grave prognostic significance. Complete heart-block was frequently compatible with a comparatively active life, and it was usually during the transition stages before complete heart-block had been finally established that syncopal attacks were most liable to occur. During periods of severe and repeated Stokes-Adams seizures the prognosis might appear to be wellnigh hopeless, but in many of these patients the attacks subsequently disappeared completely, or became less frequent, and a surprising degree of recovery was attained. In certain cases of cardiac irregularity the normal heart rhythm was interrupted by long pauses. On account of its resemblance to a-v block this condition had been termed "sino-auricular block," on the hypothesis that the excitation wave arises in the s-a node but fails to reach the auricle. This hypothesis was likely to require modification in the light of further knowledge, but served for the present to bring the condition into line with the more familiar forms of cardiac arrhythmia.

Dr. Bramwell's paper was illustrated by electro-cardiographic records from patients treated in the Manchester Royal Infirmary during the past three years, whose after-histories had been followed up to the present time.

### THE DERMATOLOGIST AS DETECTIVE.

A MEETING of the Sheffield Medico-Chirurgical Society was held on February 27th, with Dr. R. HALLAM in the chair, when Sir NORMAN WALKER read a paper entitled "The detective spirit in the diagnosis of skin diseases." As a suitable text for his subject he selected the words from Job: "The cause that I knew not I searched out." In his student days dermatology, he said, had reached the stage of observation and collection of facts. Bacteriology was then in its infancy. Many diseases then attributed to "gouty" or "nervous" conditions were now attributed to definite organisms. The method of inquiry was important. The patient should be encouraged to tell his own story. Questions should be put in such a way that it was equally easy for him to answer yes or no. The skin more than any other organ of the body, except perhaps the stomach, was subject to idiosyncrasy. Just as surgeons had personal idiosyncrasies in the way their skins reacted to antiseptic lotions, so people generally showed marked personal peculiarities of irritability to special varieties of soap. Other cases of dermatitis had been traced to feather boas cleaned with a soap powder, or furs cleaned with formalin. In regard to occupation, it is important to find out exactly what a man did. A patient, for example, who said he was a "telegraphist" was found to be a cleaner of instruments, for which he used turpentine. Certain woods, notably teak and satinwood, were liable to cause irritation in some persons; various plants, such as the *Primula obconica* and *Rhus toxicodendron*; in others cosmetics, hair dyes, and quack ointments were also frequent offenders. The lecturer concluded with the advice, "Seek till ye find. Seek and ye shall find." A vote of thanks was proposed by Professor ARTHUR HALL, and seconded by Dr. E. F. SKINNER.

### NAVAL, MILITARY, AND AIR FORCE HYGIENE.

By permission of the Medical Research Council and the Officer Commanding R.A.F. Medical Units, Hampstead, a meeting of the Naval, Military, and Air Force Hygiene Group of the Society of Medical Officers of Health was held at the National Institute for Medical Research, Mount Vernon, Hampstead, on March 19th, with the President, Major-General Sir WILLIAM MACPHERSON, in the chair. Descriptions and demonstrations were given of (1) the katathermometer and recent modifications, (2) silicosis, (3) a new dark-ground illuminator, (4) methods of selection of flying personnel.

Dr. LEONARD HILL briefly described the katathermometer and emphasized its great value in dealing with problems of ventilation. He showed that the mortality rate in factories, laundries, etc., with bad katathermometer readings was invariably high. In South African mines with bad readings a great loss of labour efficiency was found which could be remedied by improving the harmful conditions. In temperate climates the dry katathermometer was important; but in the tropics the wet katathermometer, which indicated the condition of the sweating body, was of greater value. The practical bearing of this work upon heat-stroke, labour conditions, healthy exercise, and sedentary occupations had been amply demonstrated in recent experience. Dr. SCHUSTER then

demonstrated a recent modification of the katathermometer enabling a record of the readings to be kept.

Dr. Purdy gave a demonstration of slides illustrative of silicosis. He called attention to the recent work on this subject, more especially with regard to its relationship to pulmonary tuberculosis. He showed that colloidal silica had a destructive action on endothelial cells from which the phagocytes were derived.

Mr. J. E. BARNARD demonstrated a new dark-ground illuminator of sufficiently high angle to permit the use of an objective of 1 to 2 N.A. The improvement in the image and increased resolution were demonstrated by means of specimens of *Leptospira ictero-haemorrhagiae*.

Group Captain H. M. FLACK described the methods of selection of flying personnel. The system was devised to answer the three fundamental questions: (1) Can the candidate learn to fly? (2) Will he be able to stand (a) the nerve strain, (b) the diminished oxygen tension? (3) Has he a suitable disposition for this class of combatant work? No. 3 was supplementary, and not an integral part of the medical examination. The various physiological tests employed were described in some detail, and their application in determining the answers to the above questions was explained.

### ENDOCRINES AND PSYCHONEUROSES.

At a meeting of the West Kent Medical Society held on March 9th at the Miller General Hospital with Dr. J. P. PURVIS in the chair, Dr. W. LANGDON BROWN gave a lecture on the influence of the endocrines in the psychoneuroses. He said that response to chemical stimuli was the most primitive form of defence in animals, and this was shown in the queen bee; at a certain stage of development she was strongly heliotropic, but the immediate effect of fertilization was to destroy this heliotropism and she sought the shelter of the hive. Internal secretions regulated instinctive behaviour. So it was with human beings—the instinctive behaviour of a young man in the presence of the opposite sex depended mainly on the state of his endocrine system. The activities of the endocrine glands were correlated to a large extent through the nervous system. The sympathetic system co-operated with the adrenals, thyroid, and pituitary; the parasympathetic mainly with the glands of the digestive organs and their annexes. The influences leading to hyperthyroidism might be classified under the headings of nutritional, toxic, and psychic: lack of vitamins led to diminished thyroid secretions; tonsillar sepsis and intestinal sepsis were apt to produce thyroid enlargement; and in Graves's disease the psychic factor played a large part. In the war, officers with more responsibility developed neuroses, while privates more commonly developed hysterical paralyses and mutism. Excitement and emotion caused glycosuria, especially in Jews. Fear was a perversion of the defensive mechanism of the body. The adrenals were fighting glands and made aggressive persons. In pituitary disturbance walking and talking developed late; the fat boy in *Pickwick*, in his sleepiness and his desire to make people's flesh creep, was an example of pituitary disturbance. The thyroid gland was the creator—child-bearers and artists never had myxoedema. Graves's disease increased after the air raids in London and after the San Francisco earthquake. Hypothyroidism tended to produce a resigned melancholy. In a case of acute mania which developed in a man suffering from myxoedema the mania disappeared when thyroid treatment was resumed. If the mania had been earlier there was an example of a precocious child.

### ANTE-NATAL DIAGNOSIS.

THE monthly meeting of the London Association of the Medical Women's Federation was held at the Elizabeth Garrett Anderson Hospital on March 13th, with the President, Dr. LOUISA MARTINDALE, in the chair. After preliminary business Dr. FRANCES HUXLEY read a paper entitled "Ante-natal diagnosis," in which she detailed the clinical signs of pregnancy and the dates at which they could usually be detected. She then described the various "grips" which she is in the habit of using for estimating the size of the pelvis, the lie of the child, and the relation between the size of the head and the pelvis. She discussed the date of engagement of the head in primigravidae and multigravidae respectively, and emphasized the importance of estimating the size of the foetus as the best guide to its maturity. In discussing the lie of the foetus she pointed out some of the dangers and difficulties in doing version in breech presentations, and remarked that the site of maximum intensity of the foetal heart was generally to be found below the umbilicus in such cases, rather than above, as was usually taught. A discussion followed, in which Lady BARRETT, Professor MCILROY, Dr. RORKE, Dr. RUSSELL, and others took part.

## Reviews.

### PHARMACOLOGY AND CLINICAL MEDICINE.

PHARMACOLOGY has sometimes been defined as the action of drugs on normal tissues and organisms. In reality it embodies much more than this, for it embraces the synthesis of new chemical compounds with a view to their use in medicine—branch hardly existing in this country—and our knowledge of the scientific employment of drugs in the sick-room. Pharmacology, however, is never conceived or taught as pure science, but always, directly or indirectly in relation to the patient, as the science of treatment. Professor CLARK in a bright and interesting little book, adopts as his title *Applied Pharmacology*.<sup>1</sup> In writing it his object was to bridge the gap between pharmacology and therapeutics which he thinks is too great for the student in this country to pass unaided. As matters stand at present it may be that such a gap exists, but there can be no gap if the subject is taught in the laboratory and ward at the same period of the student's curriculum, whether by the same or different professors. This is the policy universally advocated by a teachers in the subject.

Therapeutics embraces all treatment of diseased person, whether it be based on experimental pharmacology or be no more than a remnant of folklore and mere empiricism; applied pharmacology, then, should refer to that portion of therapeutics which is based on pharmacology.

Professor Clark's book is an admirable account of certain of the salient features of the action of drugs in health and disease, but the word "applied" is really unnecessary since pharmacology is an applied science. How can description of the action of morphine and strychnine, of purgatives and other drugs, be applied unless precise directions are given for their employment and for their administration under definite conditions? On the other hand, therapeutics, like politics, is not governed by a set of principles for general observance; it is still an art.

Professor Clark's book contains twenty-seven chapters. Classification in pharmacology always presents difficulties. One of two methods is adopted: either Schmiedeberg's classification into groups of substances exerting certain actions in common, or a classification according to the organs on which the drugs act. Professor Clark adopts the latter method, and his chapters deal with the action of drugs on the heart, kidney, respiration, and so on. Nevertheless, no simple classification will suffice, and separate chapters are given to alcohol, anaesthetics, disinfectants, and local anaesthetics: it is a little difficult to understand why emetine and the salicylates are included in one group, since they are in no way related to one to the other.

The book is written in an interesting fashion and is entirely free from dogmas, a feature which in our opinion makes only for good, though the modern student has a passion for his memorizing to be precise and his knowledge to be tabulated. Particularly admirable are the chapters on vitamins, radiations, immunity, and the pharmacological standardization of drugs. This book is not, I believe, intended to present a full account of treatment. It does not deal with counter-irritation, the homely poultice or camphorated oil, nor with colchicum and the essential oils; phenacetin is dealt with only in so far as it lowers temperature, a purpose for which it is not used in clinical medicine.

Professor Clark's book contains the groundwork of the rationale of treatment; it makes delightful reading and should prove of great interest to all those who treat the sick. It is the kind of book which may be picked up at odd moments and a chapter perused with interest and profit. For unless the physician has a firm grasp of the great biological truths underlying physiology and pharmacology, notwithstanding all progress in scientific medicine, he must remain an empiric. Huxley writing nearly thirty years ago said: "There is no more hopeful indication of the progress of medicine towards the ideal of Descartes than is to be derived from a comparison of the state of pharmacology at the present day with that which existed forty years ago." Clark's book is the story of the advance since that time, and the story is well told.

W. E. DIXON.

## CHARLES WHITE AND PUERPERAL FEVER.

DR. LLOYD ROBERTS will be remembered for his professional skill and for his ability not only to adapt himself to scientific progress made by others but definitely to advance such progress himself. In support of this statement it is only necessary to mention that he performed his first Caesarean section in 1867, when the mortality was 93 per cent., and his last four sections, all successful, in 1907-8. He was a great lover of old medical books, and the collection he bequeathed to the Royal College of Physicians of London was the most important its library had received since the magnificent gift of the Marquess of Dorchester's library in the seventeenth century. The memory of Lloyd Roberts will be kept alive by this gift, and also by the bequest of £500 to the Manchester Royal Infirmary to provide an annual honorarium for a Lloyd Roberts lecturer. He had worked at the Infirmary for twenty-five years and bequeathed to it a sum of £3,000. To deliver the first Lloyd Roberts lecture the trustees chose Dr. J. G. Adami, F.R.S., Vice-Chancellor of the University of Liverpool, who, remembering that Dr. Lloyd Roberts had given an address on the Manchester School of Obstetrics in 1903, chose that subject, but limited his lecture to the efforts of Charles White to prevent puerperal fever. The lecture has now, with certain additions, been published in a volume.<sup>2</sup>

Charles White (1728-1813) was a student under William Hunter in 1748 and was a friend of his brother John Hunter. He was founder and chief surgeon of the new Manchester Infirmary, where he practised surgery and obstetrics for thirty-eight years. Dr. Adami draws special attention to Dr. White's book on *The Management of Pregnant and Lying-in Women, and the means of curing, and especially of preventing the principal disorders to which they are liable*, and more especially to his remarks on self-infection in puerperal fever. This treatise, which was first published in 1773, went through five editions, was translated into French and German, and was reprinted in U.S.A. in 1793. Dr. Adami finds serious fault with the late Sir William Sinclair, who was professor of obstetrics in Manchester, because, when writing his *Life and Doctrine of Semmelweis* in 1909, he should have so minimized Dr. White's book that all the credit is given to Semmelweis. Sinclair, Dr. Adami says,

did not recognize "that practically all that Semmelweis accomplished was to demonstrate absolutely that the earlier English methods had been on sound lines (and had been introduced into the Vienna Lying-in Hospital in 1789 by Professor Boër, who had studied in England), and that reversion to those methods brought about a rapid reduction of mortality; and that the main cause of the appalling incidence of puerperal fever in the Vienna lying-in hospitals was want of cleanliness, and especially the practice of allowing students after they had come straight from the post-mortem room to examine patients without first adequately cleansing their hands. He admitted other modes of infection such as neglect to employ clean bed linen, the presence of open suppurating wounds in neighbouring beds, and self-infection—that is to say, the lochia, remnants of decidua, and blood coagula which are retained may undergo decomposition and when absorption occurs produce puerperal fever."

It may, however, be pointed out that Semmelweis was dealing mainly with the modes of infection of lying-in women from without by septic hands and instruments, whilst Charles White had dealt chiefly with auto-infection or with environmental infection arising "from foul air, filthy bedding, associated with the retention of lochia and the excreta, which in his opinion were the primary causes of puerperal fever, and he realized that when this was once developed it could be conveyed to other women."

It looks as if Charles White (1773) and Semmelweis (1843) were emphasizing two different ways of preventing puerperal fever, the former teaching that most cases were due to auto-genetic putridity and to passive unclean environment, whilst the latter, seventy years afterwards, discovered that it was mainly the direct conveyance of septic products from without into the areas where lochia and blood and placental debris accumulated which encouraged the spread of putridity. If the existence of streptococci had been known to these two observers, the importance of auto-infection would have been largely limited, and the danger of direct infection by unclean agents would have been more readily understood and accepted in this country, where the views of Semmelweis were first

made known by the late Dr. C. H. F. Routh in a paper read at the Royal Medico-Chirurgical Society in 1848 (*Transactions*, 1849).

Charles White never lost a patient under his own care in natural labour from puerperal fever, and strictly limits his statement by excluding "cases requiring the use of instruments and cases of floodings or convulsions, or cases to which he had been called into consultation." If he had realized and described more fully the risks of infection from unclean instruments and hands he would have saved many lives in the seventy years between his time and that of Semmelweis, though it is probable, that White's prophylactic views carried much more weight than Sinclair thought possible, for, as Dr. Adami says, Boër, professor of midwifery in Vienna between 1789 and 1819, had reduced puerperal mortality to 0.8 per cent. in his last year by methods which he had learnt in England. Boër's successor, Klein, was less successful, and his mortality rose to 7.8 per cent. in his first year, and to 10 per cent. between 1841 and 1846; it was not till Semmelweis discovered the great danger of direct infection by examining women during and after labour with septic hands that the value of White's teaching and his own practice of clean contact could be usefully combined.

Dr. Adami has done well to lead us back to Charles White's steps in the direction of aseptic midwifery and to reprint in the appendix much that Charles White wrote in his book. This has increased the value of his address, which should be read by all interested in obstetrics, and especially by those who deplore the persistence of puerperal mortality from sepsis. In 1919 the puerperal death rate was greater in England and Wales than in any other year since 1905; this the Registrar-General stated was "preponderantly due to septic disease," for of the 3,204 deaths assigned to "pregnancy and childbirth," 1,208, or 37 per cent., were due to puerperal infection.

## OPOTHERAPY IN EXCELSIS.

DR. L. LEMATTE, in *L'Opothérapie du Praticien*,<sup>3</sup> gives an account of the method of preparation, dose, mode of administration, and therapeutic use of a very wide variety of extracts of organs. The method of preparation consists in making a glycerin extract of the macerated organ, filtering, and then sterilizing with ultra-violet light. Directions are given for the administration of the product by mouth, by rectum, or by hypodermic injection. Accounts are given of the therapeutic use of extracts made from the brain, the thyroids, the parathyroids, the thymus, the pituitary, the kidneys, the suprarenals, the prostate, the testicles, the ovaries, the p'acenta, the mammary glands, the liver, the bile, the heart, the lungs, the spleen, the lymph glands, the marrow of bones, the stomach, and the gut.

A therapeutic index of five pages is supplied. A study of this index shows that opotherapy has the great advantage of simplicity, for adenitis is treated by extract of lymph glands, albuminuria by extract of kidneys, amenorrhoea by extract of ovaries, bronchitis by extract of lungs, cardiopathies by extract of heart, and constipation by extract of the gut. It seems only logical to suggest a further simplification, already partly achieved by polyglandular therapy: why not mince up and extract the entire animal, and the product should surely be the long-sought-for elixir of life?

The author in his preface states that since the book is written for practitioners no attempt is made to give an account of the theories which attempt to explain the action of the organs dealt with. This is rather a doubtful compliment to medical practitioners, and we think that the book would have been improved if rather more substantial evidence had been adduced to show that nine-tenths of the extracts considered have any therapeutic action whatsoever.

## THE PIRQUET SYSTEM OF INFANT FEEDING.

It is a pamphlet of seventy-four pages entitled "The feeding of healthy and sick children" Dr. EDMUND NOBEL of the University Children's Clinic in Vienna has made a painstaking attempt to explain the principles of the Pirquet system of feeding.<sup>4</sup>

As an exponent and teacher of this system since its introduction by Dr. Clemens Pirquet during the war as an educational and economic measure Dr. Nobel ought to be in

<sup>2</sup> Charles White, of Manchester (1728-1813), and the Arrest of Puerperal Fever. Being the Lloyd Roberts Lecture, Manchester Royal Infirmary, 1921. By J. George Adami, C.B.E., M.D., F.R.S. With which are reprinted Charles White's published writings upon Puerperal Fever. Liverpool: The University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd. 1922. (Demy 8vo, pp. 142; 4 plates. 5s. net.)

<sup>3</sup> *L'Opothérapie du Praticien*. By Dr. L. Lematte. Paris: A. Maloine et Fils. 1922. (Cr. 8vo, pp. 233; illustrated. Fr. 5.)

<sup>4</sup> *Die Ernährung Gesunder und Kranker Kinder*. By Privatdozent Dr. Edmund Nobel. Vienna, Leipzig, Munich: Rikola. 1923. 200y. 8vo, pp. 74; 11 figures.)

a position, if anybody is, to explain its principles and advantages. Dr. Pirquet was not satisfied that the old method of estimating and expressing food values in terms of calories was sufficiently simple to be comprehended by the lay public, and since it was a matter of vital importance to the nation that the Austrian people should realize the meaning of food values and a subsistence diet he invented his system and the unit of energy value which he called the "nem," in place of the old familiar calorie.

The word "nem" is compounded of the initials of the three words *Nahrung*, *Einheit*, *Milch*, and expresses the food value of 1 gram of average breast milk, which according to our reckoning is about 0.7 of a calorie. He has also coined the words *decanem*, *hektonem*, *kilonem*, *decinem*, *centinem*, etc., to express the value of 10, 100, 1,000 grams and 1/10 and 1/100 of a gram of milk respectively.

For our part we cannot understand why it should be considered easier to grasp the food values of different articles of diet in terms of "nems" than in terms of calories, but we are informed that it has been rendered possible by their means to enable quite young children to take an intelligent interest in the adjustment of their food intake to their physiological requirement. This may be so, but it would be equally possible to make them understand the same thing if the food values were expressed in calories and the system were sufficiently explained.

Pirquet's system has the further eccentricity that it does not recognize the weight of the child as a criterion of its food requirements, as we are accustomed to do in accordance with Rubner's original teaching; the Viennese innovation regards the sitting height (*Sitzhöhe*) as a more practical index. Pirquet estimates that the square of the sitting height expressed in centimetres gives the number of "nems" required in the twenty-four hours. To give an example: A child with a sitting height of 40 cm. requires 1,600 "nems" ( $40 \times 40$ ) in the twenty-four hours. Pirquet evidently recognizes that neither "sitting height" nor weight can give a correct measure of a child's food requirements, for he explains and defines very carefully the maximum, minimum, optimum, and balanced (aequum) requirements under individual and particular circumstances. The minimum requirement is what we understand by the requirements of basal metabolism; the maximum he defines as the most a child can take without becoming actually ill—a very poor definition, in our opinion, as it leaves out of consideration the factor of time. The optimum is about two-thirds of the maximum.

It is perhaps unnecessary to follow Dr. Nobel's interpretations farther than this so far as concerns the feeding of healthy children. The system is not likely to become popular in this country, and the fact that "balance" is taken very little into account beyond recognizing that the protein percentage of breast milk should be the standard throughout childhood—that is, about one-tenth of the total food value—will at once prejudice the system in the eyes of the medical profession on this side of the Channel. Moreover, it is hardly in conformity with the views of the majority of dietists to hold that fat and carbohydrates are interchangeable equivalents. Fats appear to have some nutritional value quite apart from their value as combustible material—perhaps as base carriers or vehicles for the fat-soluble A factor—and cannot be indefinitely replaced by carbohydrates.

In this latter connexion we are glad to note that Dr. Pirquet's system makes acknowledgement of the value of the accessory factors, a fact which bears testimony to the usefulness of the work of the Lister Institute's mission to Vienna, which was very largely for the purpose of instructing the distressful country, of which Vienna is the capital, in the newer knowledge of nutrition and the part taken by the accessory factors in scientific dietetics.

#### PSYCHO-ANALYSIS.

THE volume entitled *Introductory Lectures on Psycho-analysis* consists of a translation, carefully made by Mrs. Joan Riviere, of a series of addresses delivered by Professor SIGMUND FREUD at the University of Vienna, which, as we recently had occasion to state, have reached a fourth edition in German. They provide the most comprehensive account of the subject which has yet appeared, and the book is the best with which to commence the study of psycho-analysis.

*Introductory Lectures on Psycho-analysis.* By Professor Sigm. Freud, M.D., LL.D., Vienna. Authorized English translation by Joan Riviere. With a preface by Ernest Jones, M.D. London: George Allen and Unwin, Ltd. 1922. (Demy 8vo, pp. 395; 1 illustration. 18s. net.)

The reader cannot fail to be impressed by the ability and honesty of its writer, and by his untiring energy in seeking to unravel the motives which determine human behaviour. The style of the book is conversational, and as he proceeds the author anticipates and meets objections which may be made to his views.

The latter portion of the book, in which Professor Freud outlines his general theory of the neuroses, will be read with particular interest. There is no suggestion of finality in his treatment of the subject, for every fresh fact creates a fresh problem. Though Freud's investigations have led him to ascribe the symptoms of the neuroses to disturbances in the sexual impulse, he recognizes that the factors responsible for this state of affairs are extremely complex and variable. Some, he admits, are not preventable, and he lays stress on the influence of the inherent sexual constitution in the production of nervous symptoms. The possibilities of prevention of the neuroses by early intervention in the matter of the child's sexual development are discussed with reserve. Professor Freud holds that the value of strict supervision in childhood is small because it is helpless against the constitutional factor; that it is less easy to carry out than specialists in education imagine; that it favours an exaggerated degree of sexual repression which is harmful in its effects; and that it sends the child into life without power to resist the urgent demands of his sexuality that must be expected at puberty. Professor Freud exhibits no disposition to assume the part of a social reformer by applying the knowledge he has gained of the individual to the reconstruction of society; he is always the observer, rather than the critic or mentor. As an observer he is too acute to assume that the neuroses are the product of unfavourable external conditions of life, though these of course have their influence. He holds that though sexual deprivation ("absence of love in life"), which modern social conditions tend to impose on many people, is responsible for much unhappiness, abstinence in itself is an infrequent causal factor in the neuroses. Professor Freud has not simplified the problem of the neuroses; he makes evident his opinion that the conditions responsible are extremely intricate, and that neither their prevention nor cure is a simple matter. He certainly dissipates the myth that either marriage or "free living" will have the effect of curing a neurosis.

In these lectures Professor Freud has raised a number of problems which it will take many years to solve. His own views have been largely modified as a result of his further investigations, and it is difficult to foretell the ultimate fate of his complex theories. There can be no doubt, however, that he has made contributions of permanent value to psychology, and has enriched our knowledge of ourselves and other people.

#### THEORIES ABOUT CANCER.

DR. DUNCAN BULKLEY states that the scope of his volume, *Cancer and its Non-surgical Treatment*,<sup>6</sup> has been widened beyond his original intention, so that in addition to therapeutic considerations it deals with such divergent matters as the geographical distribution of cancer, civilization and cancer, and the biochemistry of cancer; it is in these, which may be called extraneous chapters, that the main interest of the volume lies.

The author begins with an attempt to describe the nature of cancer, but beyond the reiteration of a number of well accepted platitudes there is nothing of any value in this section. Under what is termed the positive results of laboratory investigation a statement is made which seems to be misleading. "The blood in advancing cancer," he says, "has repeatedly been shown to exhibit many manifest changes which indicate vital alterations in the action of the organs which form blood and so control the nutrition of the body and its cells." The fact, however, is that though the condition of the blood in cancer has received the most searching investigation nothing beyond the variation of a secondary anaemia has been discovered. Possibly a secondary anaemia is all that Dr. Bulkley intends to express, but if so the passage suggests the employment of a method, acceptable perhaps in the art of diplomacy, but never permissible in the science of medicine—the method of disguising a very simple statement of fact by a confusing complexity of words. Throughout the volume a tendency to this fault appears.

<sup>6</sup> *Cancer and its Non-surgical Treatment.* By L. Duncan Bulkley, A.M., M.D. New York: W. Wood and Co. 1921. (Met. 8vo, pp. vii + 472; illustrated. 6 dollars.)

Dr. Bulkley makes the dogmatic statement that laboratory experiments have negated the view that cancer is in its beginnings local; to us it seems that recent experimental work has tended to lay stress upon the influence of local irritants in certain forms of epithelial cancer, and it is actually upon this very point that the hypothesis Dr. Bulkley has set up may be shown to be untenable.

The chapters which deal with the frequency and the geographical distribution of cancer are interesting from the statistical point of view. The subject-matter is sound; much of it has been derived from F. L. Hoffmann's monumental work on the mortality of cancer throughout the world.

Dr. Bulkley draws attention to the apparently increased incidence of cancer in relation to civilization. There would seem to be little doubt about the accuracy of this observation, but to draw from it the conclusion that cancer is a disease of hypernutrition is not logically sound; it is only one possibility in a very complex problem. The section which deals with the histopathology of the disease is disappointing; much of what is stated has been derived from various authorities, but the abstracts are not given in sufficient detail to retain their original value. The account of the biochemistry is even more unsatisfactory; the discussion is introduced by the following statement: "But there is no mystery in the disease, and the real cancer problem is cleared up when we study the biochemistry of the disease." The reader begins to feel that he is on the brink of the solution of a problem which has hitherto defied investigators, and follows page after page with the closest attention, to find the subject left obscure, unless he is prepared to accept the view that cancer is a disease of deranged nutrition.

The plan followed by the author in the medical treatment of malignant disease is a combination of dietetic, hygienic, and medical measures. The dietetic part of the plan resolves itself into a vegetable diet, and menus are given for six days. The hygienic instructions are accurate and sensible, and insistence is very properly laid on the importance of a sufficiency of sleep. The medical treatment includes the use of such remedies as will incite the various organs to form and to eliminate effete elements. Where individual drugs are concerned potassium acetate appears to be that to which Dr. Bulkley attaches most importance. Various local applications are mentioned.

The volume expresses the views of a man who most implicitly believes and as faithfully practises the theories he sets out. Such a production is always interesting, but in this instance we must regretfully say that it has thrown no light upon the dark problem of malignant disease. We trust that it may not do actual harm by raising false hopes and so delaying the only treatment which so far has proved efficient—at least in the early stages of the disease.

#### FUCHS'S "OPHTHALMOLOGY."

Those of us who began the study of ophthalmology on one of the earlier editions of Fuchs's textbook will hardly recognize the new edition.<sup>7</sup> The translator has had the advantage of consultation with Professor Fuchs, and he has incorporated much matter from the thirteenth German edition, which has been prepared by Salzmann but has not yet appeared in print.

Among other changes, the section on hemianopia has been placed under disorders of the visual field, instead of, as heretofore, in the section on the optic nerve; while motor affections of the iris and ptosis have been transferred to the section on motor anomalies from their places in previous editions in the iris and lid sections respectively.

The chapters on refraction have been much enlarged and recent work on such subjects as perimetry and colour sense has been inserted; heredity is more fully discussed. Gullstrand's work on astigmatism, the cardinal points of lenses and the eye all find mention, and there is a revised table of accommodation.

The sections dealing with special diseases have been brought up to date by the incorporation of much new matter, particularly in trachoma, inclusion blepharorrhoea, necus serpens, iritis, and glaucoma—in fact, every page in this part has been revised and added to. The section on operations is improved by the addition of much recent work. In spite of these rather radical changes, the translator hopes that he

has preserved the spirit and where possible the words of Professor Fuchs and thereby maintained the standard set by the author. How far he has succeeded, it is difficult for one to say who made acquaintance with the book in a much earlier and less cumbersome edition, especially as the reviewer has not seen a recent German edition. We can honestly say that little seems to have been omitted; the work as it now stands forms a very complete textbook of ophthalmology, and as such will be very useful to the higher student of the subject. The book is so bulky that the publishers would have done well to issue it in two volumes.

#### TREATMENT OF GONORRHOEA.

The third edition of the English translation of Luys's *Text-book of Gonorrhoea*<sup>8</sup> remains unchanged in its general character. Its author is an enthusiastic advocate of urethroscopic treatment in gonorrhoea, not only in lesions of the anterior but also in those of the posterior urethra. In Luys's opinion, in every case of chronic inflammation of the urethra, whether symptoms point to lesions of the posterior portion or not, posterior urethroscopy should be carried out. The inspection should be very thorough, beginning at the neck of the bladder—paying special attention to the prostatic fossa—and ending at the meatus. By those accustomed to use other forms of posterior urethroscopes than Luys's such a piece of advice will not be well received, for the passage of a posterior urethroscope is an ordeal to which the average patient will not readily submit. However, Luys's posterior urethroscope has the advantage of passing very readily, and the discomfort experienced by the patient is comparatively trifling. As a set-off to its advantage it must be admitted that the view it furnishes, at any rate in the hands of the average observer, is inferior to that provided by other instruments.

In the chapter dealing with gonococcal epididymitis the use of injections of electrargol is strongly advocated. Luys claims that the drug has a powerful curative effect and immediately hastens resolution. He admits, however, as a drawback to the injection, that there is a temporary increase of tension and of pain, especially when infiltration is present. This drawback to electrargol injections would appear to be a very real one, since it is the rule for gonococcal epididymitis to clear up without any accidents.

An addition to the chapter on inflammation of the urethra due to other causes than the gonococcus is a section on urethritis due to *B. coli*. The author claims to have discovered a relation between a hypertrophic lengthening of the prostatic fossa and the liability to this type of urethritis. Owing to this lengthening of the fossa complete evacuation by micturition no longer takes place and infection of the stagnating urine is liable to occur. Vaccine therapy would appear to have given good results in his hands.

Additional plates and illustrations have been added in the third edition.

#### NOTES ON BOOKS.

IF in England in Elizabethan and Restoration days, cuckoldom was the standing subject of jokes, in France it was quite eclipsed by the enema syringe and the clyster. The *Joyeux Propos d'Esculape*,<sup>9</sup> by Drs. CABANÈS and WITKOWSKI, consists in great part of a study of French history and literature dealing with the use of what at first was known as a clyster, later as a lavement, and latest as a remède. Though this faecal kind of humour makes no strong appeal to the English mind, nevertheless many of the facts recorded, which show the extraordinary vogue of the enema among the French, are of interest in the history of medicine. The plays of Molière contain many allusions to this subject, and in the *Malade Imaginaire* the opening scene discloses Argan seated upon a close-stool. This indeed is hardly surprising when we remember that the King of France received members of his court under similar conditions, and that the Duchess of Burgundy had an enema administered in the very sitting-room of Louis XIV when only partly hidden by a screen. Of Henry IV of France and Navarre it is recorded that in one year he received 212 lavements, 215 purges, and was bled 47 times. It may be doubtful whether the excessive use of lavage of the lower bowel was as common among the lower orders as it was among the nobility,

<sup>7</sup> *Textbook of Ophthalmology*. By H. E. Fuchs. Authorized translation from the twelfth German edition, revised and enlarged by Alexander Duane, M.D. Seventh edition. Philadelphia and London: J. B. Lippincott Company. 1923. (Med. 8vo, pp. xv + 937; 455 figures, 42s. net.)

<sup>8</sup> *A Textbook of Gonorrhoea and its Complications*. By Dr. G. Luys. Translated and edited by A. Foerster, M.R.C.S., L.R.C.P. London. Third revised edition. London: Baillière, Tindall, and Cox. 1922. (Roy. 8vo, pp. xvi + 40; 5 plates, 212 figures, 25s. net.)

<sup>9</sup> *Joyeux Propos d'Esculape*. By Drs. Cabanès and Witkowski. Paris: Librairie E. Le François. 1922. (Imp. 16mo, pp. 348; 47 figures. Fr. 9.)

but it appears that a record exists of a suit brought in the seventeenth century by a nurse against a Canon of Troyes for payment of her fees for the administration during two years of 2,190 clysters, and it is certain that up to a very recent period the appearance in a French farce of an apothecary with a pantomimic syringe was sure to provoke roars of laughter. The subject is illustrated by a number of bad reproductions of old plates and of some modern ones, in which the basest part of the human body is much in evidence. The article entitled "Clysteriana" occupies a large part of the volume, which also contains a number of anecdotes more or less medical and less rather than more humorous to the English reader.

In his book on *Diseases of the Heart*<sup>10</sup> Dr. HARRIS attempts to give to students and practitioners "a complete account of cardiology, old and new, in as concise a form as possible." This laudable object is difficult of attainment in a small book of about 200 pages, and we fear that to make it profitable for students much of the precision of detail, which apparently has been sacrificed to brevity, would require to be incorporated. For instance, in the section dealing with the analysis of jugular tracings it is twice stated that "once the c wave is recognized the other waves are easily made out," and again, "before c, a is expected, and after c, v." Analysis of these tracings is not always easy for the experienced, and for the student more guidance is required. Electro-cardiograms are freely used for purposes of illustration, but better examples might have been obtained for most of the conditions, while some are misleading. Figs. 25 and 26, illustrating paroxysmal tachycardia, are quite useless for any purpose. A lack of essential detail is also observed in the chapter on treatment. Under the heading of "doses," digitalis is recommended in certain doses, but the preparation of the drug is not indicated, while nine other substances are mentioned without stating the doses of any. The general aim of this book is commendable, but one gets the impression that it has been sent too hurriedly to the press. If a subsequent edition is called for it could be made much more useful by careful revision.

A volume of more than 300 pages, comprising the full report of the Fifth International Neo-Malthusian and Birth Control Conference held in London last July has just been issued.<sup>11</sup> The Conference was called and organized by a body now known as the New Generation League, and a report of the proceedings appeared in our issue of July 22nd, 1922 (p. 132). Besides the medical section there was a section on contraceptives, which held a private afternoon session open to members of the medical profession only; it was attended by 164 medical practitioners. Notwithstanding the privacy of this session, a verbatim report appears in the volume now published. The speakers were the President of the Section, Dr. Norman Haire, who opened the proceedings with a paper, Sir Arbuthnot Lane, Dr. L. Myer, Dr. M. I. Finucane, Dr. W. H. B. Stoddart, Dr. Killick Millard, Dr. Abraham Wallace, Dr. Frances Huxley, Lord Dawson, Dr. F. Goldstein (of Berlin), and Dr. Nyström from Sweden. At the conclusion of the session a resolution was passed expressing the view that "birth control by hygienic contraceptive devices is absolutely distinct from abortion in its physiological, legal, and moral aspects"; and that "there is no evidence that the best contraceptive methods are injurious to health or conducive to sterility." This was passed with three dissentients. The other sections appear to be reported with equal fullness.

## CRIMINAL RESPONSIBILITY.

Two documents for submission to the Committee appointed by the Lord Chancellor, under the chairmanship of Lord Justice Atkin, have been issued during the last few days. The one is a memorandum of evidence on legal responsibility for crime, prepared under the authority of the Council of the British Medical Association for submission to the Committee; the other is a report, also for submission to the Committee, made by the Medico-Psychological Association.

Lord Justice Atkin's Committee is instructed to report upon what changes, if any, are desirable in existing law, practice, and procedure relating to criminal trials in which the plea of insanity as a defence is raised, and as to the nature of the changes which should be made.

The subject has engaged the attention of the British Medical Association for a good many years, and in 1913 a special sub-committee of the Medico-Political Committee was appointed to consider the present state of the law with regard to legal responsibility for crime. In due course it presented a report, which was approved by the Annual Representative Meeting in 1915, and the memorandum now issued has been based on that report. It was finally approved by the Council at its meeting on February 14th last. The Association has also arranged to give evidence to Lord Justice Atkin's Committee, and has nominated witnesses as mentioned in the concluding paragraph of the memorandum.

The following is the Memorandum of Evidence prepared by the Council of the British Medical Association for submission to Lord Justice Atkin's Committee.

### MEMORANDUM OF EVIDENCE ON LEGAL RESPONSIBILITY FOR CRIME,

*Submitted by the British Medical Association.*

#### (A) HISTORICAL.

The Council of the British Medical Association on learning that the Lord Chancellor had appointed a Committee to consider and report upon what changes, if any, are desirable in the existing law, practice, and procedure relating to criminal trials in which the plea of insanity as a defence is raised, and whether any, and if so what, changes should be made to the existing law and practice in respect of cases falling within the provisions of Section 2, Sub-Section 4, of the Criminal Lunatics Act 1881, instructed the Medical Secretary of the Association to approach the Secretary of that Committee stating that the Association would be glad of an opportunity of giving evidence before that Committee. A favourable reply having been received, a Special Sub-Committee of the Association was set up, consisting of Sir Jenner Verrall, LL.D. (Chairman), Dr. J. W. Bone, Dr. H. B. Brackenbury, Dr. H. C. Bristowe, Mr. Roland Burrows, LL.D., Mr. E. J. Denville, O.B.E., Dr. R. Langdon-Down, Dr. James Scott, Lt.-Col. T. Knowles Stansfield, C.B.E., Dr. W. B. Crawford Treasure, and Mr. E. B. Turner.

As a result of the Central Association for Mental Welfare having approached the Association with a view to co-operation, 3 members of that Association, viz., Dr. E. Prideaux, Dr. F. C. Shrubbsall, and Dr. A. F. Tredgold, were added to the Sub-Committee.

It is understood that evidence dealing with the position of prisoners committed for trial but not yet tried, will be permissible, and such evidence is submitted in para. VIII. hereof.

#### (B) MEMORANDUM OF EVIDENCE.

The Memorandum of Evidence which the Sub-Committee, on behalf of the Council of the Association, desires to lay before the Committee appointed by the Lord Chancellor is as follows:—

*Sub-Section 4 of Section 2 of Criminal Lunatics Act, 1881.*

I. The Council, realising its very great importance, has given careful consideration to this matter, and has come to the conclusion that it cannot suggest any improvement in the method laid down in Sub-Section 4 of Section 2 of the Criminal Lunatics Act 1881 which reads as follows:—

(4) In the case of a prisoner under sentence of death, if it appears to a Secretary of State, either by means of a certificate signed by two members of the visiting committee of the prison in which such prisoner is confined, or by any other means, that there is reason to believe such prisoner to be insane, the Secretary of State shall appoint two or more legally qualified medical practitioners, and the said medical practitioners shall forthwith examine such prisoner and inquire as to his insanity, and after such examination and inquiry such practitioners shall make a report in writing to the Secretary of State as to the sanity of the prisoner, and they, or the majority of them, may certify in writing that he is insane.

*Legal Responsibility for Crime.*

II. The Council of the Association is of opinion that the following might be accepted by the Medical Profession as a fair definition of responsibility for crime:—

An act may be a crime although the mind of the person who does it is affected by disease or defective power if such disease or defect does not in fact prevent him:—

(a) from knowing and appreciating the nature and quality of his act or the circumstances in which it is done; or

(b) from knowing and appreciating that this act is wrong; or

(c) from controlling his own conduct unless the absence of the power of control is the direct and immediate consequence of his own default;

but no act is a crime if the person who does it is at the time it is done prevented either by defective mental power or by any disease affecting the mind:—

(a) From either knowing or appreciating the nature and quality of his act or the circumstances in which it is done; or

(b) From either knowing or appreciating that the act is wrong; or

(c) From controlling his own conduct, unless the absence of the power of control is the direct and immediate consequence of his own default.

N.B.—“Wrong” may mean (a) morally wrong; (b) illegal.

*Evidence as to Mental Condition of Accused Persons.*

III. The Council of the Association is of opinion that the following Standing Order issued by the Prison Commissioners, which is understood to apply to prisoners who have been committed for trial but not yet tried, should be embodied in the official Prison Rules:—

302. (1) In the case of an untried prisoner, especially if charged with an offence of a grave nature, the Secretary of State desires that the prisoner's insanity shall, if possible, be publicly decided by the verdict of a jury, and that the prisoner shall, for this purpose, be left to stand his trial, unless there be strong reasons to the contrary.

(2) When immediate removal to an asylum is unnecessary, the Governor will merely forward the report of the Medical Officer to the Prison Commissioners, saying that it is not proposed to obtain the usual certificate of insanity, and will state the probable date of trial.

(3) When removal to an asylum appears to the Medical Officer to be, for special reasons, necessary, the usual certificate will be obtained and forwarded, as directed in Order 301. In filling up the certificate the probable date of the trial will be added to the particulars of commitment, and the report of the Medical Officer, setting out the nature of the insanity and the necessity for immediate removal, will be enclosed, together with a newspaper report of the Police Court proceedings. If this latter is not procurable, a short report of the particulars of the prisoner's crime will be furnished.

(4) When a prisoner awaiting trial has been certified to be insane, or is believed by the Medical Officer to have been insane on reception, or when there is any doubt as to his mental condition, the Medical Officer will furnish a report in writing to that effect to the Governor, who will forward it to the Clerk of Assize or Clerk of the Peace, as the case may be. In all cases when there is any reason to suppose that questions are likely to arise in Court as to the mental state of the prisoner, the Medical Officer will attend to give evidence if required, whether he gets a subpoena or not.

IV. The Council of the Association suggests that, wherever a report from the prison Medical Officer as to the mental state of the prisoner is communicated to the Clerk of the Court, it should be the duty of the Clerk to furnish a copy of the Report to Counsel or the solicitor acting for the prosecution and defence respectively.

*Position of Persons found “Guilty but Insane.”*

V. The Council of the Association is of opinion that every person found “Guilty but Insane” should have the same right of appeal as is conferred by the Criminal Appeal Act on persons convicted on indictment; provided that if in any appeal brought by such person the Court should be of opinion that the verdict should be set aside so far as the finding of insanity is concerned, the Court should have the power to order a new trial.

*Persons found “Unfit to Plead.”*

VI. The Council of the Association is of opinion that persons found “Unfit to Plead” by the verdict of a jury and ordered to be detained, should be entitled, whilst so detained, at any time on proper conditions to apply to a Judge of the High Court to order the re-trial of the issue as to fitness to plead.

(It is understood that the rules by which such applications would be governed would need to be framed by the appropriate authority.)

*Medical Officers of Prisons.*

VII. The Council of the Association has given very careful consideration to the question of the status of Medical Officers of Prisons and wishes particularly to emphasise that it is desirable that such Medical Officers should have had experience in the diagnosis and treatment of disorders and defects of the mind.

*EVIDENCE BY SPECIAL SUB-COMMITTEE OF THE BRITISH MEDICAL ASSOCIATION.*

VIII. The foregoing is in substantial agreement with the policy adopted by the British Medical Association in 1915.

The Special Sub-Committee of the Association is of opinion:—

(1) That in the interest both of the community and of persons charged with or convicted of offences, it is desirable that, where there is reason to believe that the accused person suffers from mental defect or disease, machinery should be provided for the independent and impartial mental examination of the accused person.

(2) That the present method, by which medical evidence is presented by the Prosecution and the Defence in cases in which the accused is a person of means, is bewildering rather than helpful to Judge and Jury and liable to lead to miscarriage of justice; that a similar miscarriage of justice may result in the case of persons without means owing to the absence of facilities for expert psychological examination.

(3) That some such scheme as follows might be adopted:—

(a) That a Panel should be formed consisting of medical practitioners with expert knowledge and experience of psychological medicine and of recognised standing, and that any accused or convicted person in whose case there is reason to consider that mental defect or disease is present should be referred to such panel for examination.

(b) That in the case of any such person charged with an offence which is punishable upon summary conviction such examination should be made by one or more members of the panel. That in the case of any such person charged with an offence which is punishable by death or a long period of penal servitude such examination should be made by not less than three members of the panel.

(c) That the report of such examination should be furnished to Prosecution and Defence before the trial and that at the trial evidence should be tendered in person by the expert or experts who examined the accused and should be considered by the Court in deciding the responsibility or otherwise of the accused.

*(C) NAMES OF WITNESSES OF THE ASSOCIATION.*

The following Witnesses have been appointed to give evidence on behalf of the Council of the Association before the Committee appointed by the Lord Chancellor:—

SIR JENNER VERRALL, LL.D., L.R.C.P., M.R.C.S., Consulting Surgeon, Sussex County Hospital—Chairman of the Insanity and Crime Sub-Committee, British Medical Association.

ROLAND BURROWS, LL.D.—Barrister-at-Law.

R. LANGDON-DOWN, M.B., B.Ch., Physician to the National Association for the Welfare of Feeble Minded.

E. PRIDEAUX, L.R.C.P., M.R.C.S., Mental and Neurological Inspector, Ministry of Pensions; late Assistant Medical Officer, Banstead Asylum.

JAMES SCOTT, M.B., C.M., Ed., late Governor and Medical Officer, H.M. Prison, Holloway; and late Medical Officer, H.M. Prisons, Brixton, Holloway, Newgate, etc.

T. KNOWLES STANFIELD, C.B.E., M.B., C.M. Ed., Honorary Lt. Col. R.A.M.C.; Consultant in Nervous and Mental Diseases to the Eastern Command; late Medical Superintendent, London County Mental Hospital, Bexley.

A. F. TREGOLD, M.D., Consulting Physician, National Association for Welfare of the Feeble Minded; Medical Expert to Royal Commission on Feeble Minded; Physician and Neurologist to Royal Surrey County Hospital; Neurological Specialist to the Ministry of Pensions; Consulting Mental Specialist to the Willesden Education Authority.

REPORT OF THE MEDICO-PSYCHOLOGICAL  
ASSOCIATION.

The Medico-Psychological Association of Great Britain and Ireland at its meeting on February 22nd adopted the report of its committee on criminal responsibility. The committee included medical superintendents of asylums, several persons now or formerly commissioners in England and Scotland, or Lord Chancellor's visitors, several persons concerned with the feeble-minded and with prison administration, and two barristers. The report is in form a memorandum to Lord Justice Atkin's Committee.

At the outset the opinion is expressed that the law as at present interpreted is unsatisfactory, and does not always permit the best and fullest evidence of a prisoner's mental condition to be laid before a court and jury.

*The Judges' Rules, 1813.*

Reference is made to the rules in M'Naghten's case (1843), which, it is stated, have for many years been the subject of cogent criticism both by medical men and by juries. Their survival is attributed to three causes: (1) the failure to propound an acceptable alternative; (2) the fact that on numerous occasions individual judges have disregarded and declined to act on them; and (3) the knowledge, shared by judges and juries alike, that although a person may be found guilty and sentenced, his case will be carefully reconsidered by experts appointed by the Secretary of State in accordance with the Criminal Lunatics Act, 1884, and that action will be taken accordingly notwithstanding the findings of the court.

The rules in M'Naghten's case are contained in the answers made by the judges to certain questions put to them by the House of Lords. The most important of the rules in the present connexion is the reply made to questions 2 and 3, which asked:

"(2) What are the proper questions to be submitted to the jury when a person afflicted with insane delusions respecting one or more particular subjects or persons is charged with the commission of a crime (murder, for instance) and insanity is set up as a defence; and (3) in what terms ought the question to be left to the jury as to the prisoner's state of mind at the time the act was committed?"

The answer to these two questions, which the judges took together, contains the following passage:

"The jurors ought to be told, in all cases, that every man is presumed to be sane, and to possess a sufficient degree of reason to be responsible for his crimes, until the contrary be proved to their satisfaction; and that, to establish a defence on the ground of insanity, it must be clearly proved that at the time of the committing of the act the accused party was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it [sic], that he did not know he was doing what was wrong."

*The Growth of Knowledge.*

The committee observes that insanity is admitted to be incapable of precise definition, but accepts as a rough and ready criterion the definition of a lunatic in the Lunatics Act, 1890, as "an idiot or person of unsound mind." On this part of the subject the committee makes the following pronouncement:

"These rules are not wrong in holding that irresponsibility is only an inference that may or may not be drawn from insanity; where they err is in attempting to define precisely the conditions under which the inference is legitimate. They identify responsibility with knowing and reasoning, whereas any medical man with experience of the insane must know of many persons as to whose insanity (and irresponsibility) there can be no possible doubt, who have realized the nature and quality of their act, have known that it was contrary to the law, human and divine, and have shown remarkable cleverness in carrying out their object."

The committee assumes that the judges framed rules in accordance with what they were advised was the generally accepted medical view as to the nature of insanity. The crux of the situation seems to be that the conception of unsoundness of mind implied in the questions and answers is now obsolete. The committee says:

"Unsoundness of mind is no longer regarded as in essence a disorder of the intellectual or cognitive faculties. The modern view is that it is something much more profoundly related to the whole organism—a morbid change in the emotional and instinctive activities, with or without intellectual derangement. Long before a patient manifests delusions or other signs of obvious insanity he may suffer from purely subjective symptoms, which are now recognized to be no less valid and of no less importance in the

clinical picture of what constitutes unsoundness of mind than the more palpable and manifest signs of the fully developed disorder, dementia."

The Scots law is similar to that of England, and the position seems to have been well summed up in 1907 by the then Lord Justice General, Lord Dunedin:

"In one sense no one can say what insanity is. I do not think if we had all the doctors here who are learned on the subject that any two of them would agree on a definition. It is quite certain that what may be called the scientific view on insanity has greatly altered in recent years, and courts of law, which are bound to follow, so far as they can, the discoveries of science and results of experience, have altered their definition and rules along with the experts. . . . Acts of Parliament cannot deal with scientific opinions, and therefore it is left to juries to come to a common-sense determination on the matter, assisted by the evidence led and any direction which the judge can give."

The change of opinion, the committee states, explains how at the present day a medical witness may find a real difficulty in satisfying the court when pressed to give a categorical Yes or No, and secondly the impracticability of attempting to frame any other formula. It considers it reasonable to propose that the facts as to insanity should be put before the court unhampered by any formula, and states:

"Elucidation of all the relevant facts, including such conditions of defective control as occasion epilepsy, impulses, obsessions, hysterical states, drug addiction and alcoholism in their bearing upon an alleged crime, would, in many cases, be necessary, and medical witnesses experienced in the care and treatment of the insane could give assistance to the court in that direction. A jury, upon the facts so presented, with such guidance as the judge might feel it necessary to give, should have no insuperable difficulty in reaching a correct conclusion."

"In our view the law should be framed so as to allow the medical witness alleging insanity to make it clear that the facts observed by himself, supplemented by other evidence before the court, form in his mind a coherent clinical picture of mental disorder; and he should be in a position to state that the prisoner's criminal act is symptomatic of, or at least consistent with, such a condition. His evidence should enable a jury to find that, even if there should be no apparent logical connexion between the prisoner's mental derangement and his criminal act, it is reasonable to conclude that both form part of his mental unsoundness, and it is important that that evidence should be placed before them as fully as possible. According to the present practice, experts on this question are subject to restrictions which are not imposed on experts on other matters. There does not appear to be any sufficient reason why a medical man should not be allowed to state his grounds for arriving at an opinion in his own way, subject always to the fullest cross-examination by the other side and by the court."

*Recommendations.*

The conclusions of the committee are as follows:

(i) The legal criteria of responsibility expressed in the rules in M'Naghten's case should be abrogated, and the responsibility of a prisoner should be left as a question of fact to be determined by the jury on the merits of the particular case.

(ii) In every trial in which the prisoner's mental condition is in issue the judge should direct the jury to answer the following questions:

- (a) Did the prisoner commit the act alleged?
- (b) If he did, was he at the time insane?
- (c) If he was insane, has it nevertheless been proved to the satisfaction of the jury that his crime was unrelated to his mental disorder?

(iii) We would further suggest that the present practice of dealing with persons who are found insane upon arraignment is unsatisfactory and might be reconsidered. As the law stands a finding of insanity upon arraignment may result in a man—conceivably unconnected with and innocent of the offence with which he is charged—being sent to a criminal lunatic asylum. Experience shows that it is always best, if possible, to let the prisoner stand his trial and plead. This course does away with his after grievance that he was never convicted of the offence with which he was charged, and that, in fact, he never was tried for it. In the vast majority of cases there is no reason to doubt that the man did commit the act, but the fact that the crime was never brought home to him, and that, being found insane, he has been ordered to be detained during His Majesty's pleasure, does give him a grievance of which he makes the utmost use, and to which it is difficult to give a satisfactory answer.

When a person is found unfit to plead we would suggest that a plea of "Not Guilty" should be recorded by the court, and the trial on the facts allowed to proceed—in his absence if he cannot properly be present in court, arrangements being made for him to be represented by counsel and solicitor.

We presume that to enable this course to be adopted some amendment of the Criminal Lunatics Act, 1800 (39 and 40 Geo. III, c. 94), sec. 2, would be necessary.

(iv) We would also suggest that the law be amended to enable the verdict now expressed as *Guilty but insane* to rank as a conviction for the purposes of appeal to the Court of Criminal Appeal.

(v) We are of opinion that it would not be practicable to have medical assessors to the court in cases where insanity is raised as a defence to a criminal charge. We think, however, it might be possible to have a panel of accredited experts appointed, any of whom could be called on by the court to give evidence, subject to cross-examination by either side, and without any derogation from the right of either side to call its own expert witnesses.

Finally, the committee expresses itself against any amendment of the Criminal Lunatics Act, 1884, the provisions of which it looks upon as both humane and necessary. The report is signed by Dr. Nathan Raw (chairman of the committee), Professor G. M. Robertson (president), and Dr. R. Worth (honorary general secretary) of the Medico-Psychological Association.

### THE IRRITATIVE TYPE OF LETHARGIC ENCEPHALITIS.

We are indebted to Dr. A. K. Chalmers, M.O.H. Glasgow, for a copy of a memorandum by himself and Dr. A. S. M. Macgregor, senior assistant in the Public Health Department, Glasgow, on an outbreak of lethargic encephalitis which began there in February and included a number of cases of a severe type showing uncommon irritative features.

#### *Incidence of the Disease in Glasgow.*

It is, they state, difficult to give an idea of the incidence of the disease in Glasgow during the past few years because the cases notified in 1921 and 1922 mainly showed the sequelae of missed infections in 1920. The following table gives the admissions to certain fever hospitals during the five years 1918-22; many other cases were treated in the general hospitals, especially during 1920, when the affection was last prevalent in Glasgow. It appears from the table that there was a small peak of incidence during the fourth quarter of 1919, and another during the second quarter of 1920.

*Admissions of Cases of Encephalitis Lethargica to Belvidere and Ruchill Fever Hospitals, Glasgow, between 1918 and 1922.*

	1918.	1919.	1920.	1921.	1922.
First quarter ...	—	6	6	2	1
Second quarter ...	4	3	22	5	4
Third quarter ...	3	1	3	1	—
Fourth quarter ...	—	11	3	4	—

Encephalitis lethargica was made notifiable in Glasgow in 1918; evidence of its incidence based on notification is very unreliable, because undoubtedly the number (63) notified in 1920 did not reveal the extent of the epidemic, as many cases sickening during the year were only recognized and reported one, two, and even three years later, on account of typical sequelae. It is thought probable that the notifications for 1923 will form a more accurate index of the prevalence of the disease, because of the experience gained in 1920. In the cases which began to be observed towards the end of February last the irritative stage has tended to be more pronounced and more prolonged and the febrile disturbance greater than in such sporadic cases as have been met with prior to and since 1920, the last period of undoubted prevalence in the city. In 1920 many of the cases sickening in the spring and early summer were of somewhat severe type with fever, sudden onset and spasmodic or "choreiform" muscular agitation during the illness, tending to be followed by paresis or paralysis of groups of muscles. There is now a recurrence of this type, apparently in greater number and, in some instances, in even more severe form.

The sudden appearance of cases of this variety was observed and reported simultaneously by Dr. Leonard Findlay, Dr. Iry McKenzie, and others at the same time as one or two such patients were admitted to Belvidere and Ruchill Fever Hospitals. The account of the salient clinical features is based on reports furnished by Drs. Findlay and

McKenzie, Drs. Archibald and Elliott of Ruchill and Belvidere Hospitals, and on investigations by the public health staff.

Since the beginning of February 38 cases of lethargic encephalitis have been notified or reported in Glasgow, one sickening in December, 1922, 5 in January, 1923, and the remainder in February. The ages of the patients varied from 1½ to 56 years, 22 being over 15 years of age; 8 have died after illness lasting from six to seventeen days. The cases have occurred sporadically, being distributed throughout the city and quite unassociated with one another; in no instance has more than one member of a family been affected.

#### *Symptoms in Present Outbreak.*

Clinical data are available in respect of 33 patients; in a number of them the symptoms approximated to the classical description of the affection, irritative symptoms being slight or absent, neuro-muscular disturbance confined to the ocular muscles, and drowsiness (or lethargy) a prominent feature. The majority, however, have presented a pronounced irritative stage, with excitement, delirium, and restlessness, especially at night, sometimes requiring forcible control, while spasmodic twitching or choreiform movements of the limbs or of the whole body have been a marked feature of most of the cases, and have been very violent in some. The onset has commonly been that of an acute infection, and the temperature has varied from 100° to 102° F., but was occasionally higher. Hyperpyrexia has occurred in fatal cases. Restlessness and twitching movements, when prominent, have appeared early, but in some cases there has been a preliminary period of a few days to a few weeks marked by headache, sleeplessness, neuralgic pains in the limbs, trunk, or face, giddiness, and occasional vomiting. Ophthalmoplegic symptoms, of which the chief is diplopia, are typical of the disease, but may be transient and therefore absent at the time of examination.

While this brief description may be regarded as fitting loosely the prevailing sharper type of case, others have occurred in which the acute toxic symptoms have been of excessive severity, as in the following case under Dr. Iry McKenzie's care in the Eastern District Hospital, Glasgow.

R. R., female, aged 19 years; onset of illness on February 13th, with sleeplessness and restlessness; double vision developed on February 15th, when she became delirious. Next night she was delirious and highly fevered. On admission to hospital the temperature was 103° F., and the patient appeared very ill; she was very restless, constantly coming out of bed and inclined to be resistive. She took her nourishment well but did not sleep. Her attention could always be sustained, but she did not speak. She did not sleep even with sedatives till the night before she died, except for one hour. There was slight squint, no abnormality of pupils, reflexes normal, no paralysis. The patient had twitching of legs, arm, and body. There was no lethargy and no great psychomotor excitement. She died on February 23rd.

It will be noted that the patient died in the acute restless stage. The following example of a prolonged irritative restless period is also from notes furnished by Dr. Iry McKenzie.

Mrs. B., aged 33 years; onset of illness on night of February 16th, with symptoms of chill with pain in right shoulder, restlessness, sleeplessness, and general twitching movements. Very ill on admission, with temperature 101° to 103° F. She had jerky tremulous movements not at all resembling chorea, more like clonus in the arms. There was also twitching of the face. She complained of headache, but had no squint or diplopia. Was very sleepless and restless, constantly trying to get out of bed; very delirious, but could always be recalled from delirium with ease. The movements have gradually become less; she has slept under paraldehyde and is no longer delirious. No evidence of lethargy.

Acute cases of this nature where lethargic symptoms are absent have been exceptional, but the cases are given to show the severity and duration to which the irritative stage may reach.

The signs and symptoms referable to the involvement of the central nervous system are extremely varied, and it has been found difficult to give a concise description of its onset and progress. The former may be acute or gradual and the latter brief or prolonged, with resulting exhaustion and mental impairment. The following case, reported by Dr. Archibald, Belvidere Fever Hospital, and Dr. R. S. Fullarton, is given as being probably as typical as any in the present outbreak.

M. M., female, aged 8 years. On February 4th she complained of noises in her ears; on the 7th the eyes were congested and looked as if "she were taking measles." On the 8th the patient's mother noticed that her legs were twitching, and could feel the "jerks" of the thigh muscles. At night she had hallucinations and was very restless and "delirious," also complaining of pains

in the calves of the legs. Admitted to Belvidere Hospital on the same day; on observation there the patient's illness fell into stages, the first marked by a period of delirium, restlessness (child getting out of bed), with lethargy, mental confusion, and choreiform movements, first of the left side of the body, then of both sides; during this time the temperature was rising to 101-102° F. This period lasted for about six days from its onset. The next stage was one of constant drowsiness, lessening of choreiform movements, absence of excitement, and dazed facies, lasting about a week, during which the temperature, at first sustained, began to remit. This was followed by a period during which the child showed morning brightness and evening drowsiness, and absence of choreiform movements; the temperature was intermittent, with evening rises to 100-101° F. This lasted for about ten days, after which the temperature became normal and the child apparently well.

#### General Summary.

The cases do not readily fall into definite clinical types; particular signs or symptoms may be absent or variously combined in different patients with great variation in their duration and intensity. Among these the following are selected for mention, though they are by no means always present in individual cases of the severer types of illness:

1. *Symptoms on Onset.*—The initial complaint may be of rheumatism or neuralgic pains in a limb, the shoulder, neck, face, or abdomen, trifling or severe. Headache is common, and vomiting occasional. Sleeplessness is a very prominent and early symptom. One or two have commenced with "influenza" or sore throat.

2. *Fever.*—In the acuter cases there may be fever from the beginning, continuous at first and later intermittent. In a few cases, usually fatal, there may be hyperpyrexia. Many patients, however, although showing much motor disturbance and delirium, have little fever.

3. *Delirium and restlessness* may be extreme, requiring forcible control. A feature of the delirium is that the patient can be roused and can answer questions sensibly enough, though there may be some mental confusion. Restlessness may be a continuous feature or may alternate with drowsiness. When present it occurs, or is worse, during the night.

4. *Involuntary muscular movements* are variously described as twitching, spasmodic, choreiform, involving the feet, the limbs, or the whole body. In a severe case the body may be jerked from flexion to extension and vice versa, and the patient may have to be held in bed. Twitching has been definitely present in 18 cases in the present series. It may, however, be so slight as to be overlooked unless watched for. In milder cases it is not unlike the spasmodic contractions of tic. Spasticity is associated with its presence.

5. *Insomnia* is an almost constant feature, sleeplessness being an early and noticeable symptom in most cases. It may precede onset of twitching by a few days.

6. *Lethargy* may be present early or may succeed the irritative stage. In a few of the patients it was not a prominent feature, but the great majority had this symptom in greater or less degree. The face may assume a dull mask-like expression.

7. *Ocular Phenomena.*—Diplopia is the most frequent of these and may be persistent or transient; ptosis may be present on one or both sides, and in one or two instances nystagmus has been observed. The appearance and reaction of the pupils vary considerably.

## OXFORD CONTRIBUTORY HOSPITAL SCHEME.

STATEMENT BY DR. WILLIAM COLLIER.

We have received from Dr. William Collier an account of how the Oxford hospital scheme\* has fared during the past two years. He writes:

The scheme was started in September, 1920. A contributor is asked to subscribe 2d. a week, children of wage-earning age 1d. until they are earning an adult's wage. In the case of married couples, when the husband and wife each subscribe 2d. a week, their children are entitled to treatment up to wage-earning age. Every care is taken to prevent those who are in a position to pay for adequate medical advice from joining. No contract is made with the contributors.

In 1921 the scheme brought the hospital a little over £17,000, but we had yet to enrol a number of villages and firms. In 1922 the scheme brought the hospital a little over £23,000. When one learns that in 1913 the total income of the hospital from all sources amounted to £9,559 one realizes how much those who use our hospitals can do towards keeping them on a voluntary basis.

We were told at the outset it would be impossible to get agricultural labourers voluntarily to subscribe as much as 2d. a week; they have done so, and in spite of the enormous reduction in their wages they still continue to do so.

We have organized Hospital Aid Committees in 295 villages; and in the towns, including Oxford itself, we have Aid Committees in every parish. In this way over two thousand people are working for, and are interested in, the maintenance of our hospital on a voluntary basis, who a few years ago scarcely gave the hospital a thought. A very large number of meetings have been organized in the villages. At these meetings the speakers explain why both surgical and medical work has become so much more expensive, why it is important to keep our hospitals on a voluntary basis, why those who are present should join the scheme, and so on.

Perhaps one of the most striking examples of the way in which those can help who have a mind to is the fact that last year the employees of two shops in Oxford, from which the hospital obtained nothing in 1919, contributed between them £230 5s.

The total cost of working the scheme comes to a little less than 4½ per cent. of the amount collected.

Dr. Collier includes the following financial statement:

#### RADCLIFFE INFIRMARY AND COUNTY HOSPITAL, OXFORD.

##### WEEKLY CONTRIBUTION SCHEME.

##### Financial Statement, 1921, 1922.

1921.	£	s.	d.	1922.	£	s.	d.
Received during the year and to Jan. 10, 1922	...	...	...	Received during the year and to Jan. 10, 1923	...	...	...
...	16,281	11	1	...	21,533	5	7
Received during 1922 in respect of 1921	...	...	...	Amount received for 4th quarter after Jan. 10, 1923	...	...	...
...	1,150	4	3	...	1,521	4	1
...	£17,431	15	4	...	£23,059	9	8

Increase on year, £5,627 14s. 4d.

##### Expenditure.

1921.	£	s.	d.	1922.	£	s.	d.
Appeals	...	...	...	Appeals	...	...	...

...	£1,464	14	3	...	£1,038	8	1

Decrease of expenditure, £396 6s. 2d. Proportion of expenditure to total receipts, 4½ per cent.

Dr. Collier sends a list of some typical examples of increased incomes from various places, from which we make the following selection (the first two places are market towns, the rest villages):

#### Typical Examples of Increased Income from Market Towns and Villages.

Place.	Income from all Sources.		
	1913.	1920.	1921.
	£ s. d.	£ s. d.	£ s. d.
Abingdon	69 11 7	191 17 2	1,001 4 9
Witney	102 2 0	236 14 9	1,433 12 7
Kidlington	15 6 0	59 14 1	291 16 8
Easton	25 10 0	23 10 0	214 13 5
Bampton	21 3 6	38 12 1	223 17 9
Leafeld	12 17 5	47 1 9	130 15 8
Long and Little Wittenham	14 14 6	42 11 2	156 13 11
Garsington	10 12 8	16 0 5	136 15 2
Kirtlington	8 10 5	22 8 7	183 9 1

Dr. Collier also sends some examples of the increased income from employees. Thus the contributions received from men employed by the Great Western Railway Company at Oxford rose from £35 in 1914 to £116 in 1920 and £178 in 1921; from those engaged by the University Press from £39 in 1914 to £129 in 1921; and from the employees of a motor manufacturing company from £64 in 1920 to £106 in 1921.

THE staff of the Buffalo General Hospital has started the publication of a Bulletin, to contain records of cases occurring in the hospital. The first number, which is before us, bears the date January, 1923; it is very well got up, the illustrations are excellently reproduced, and all the cases are well worthy of record.

# British Medical Journal.

SATURDAY, MARCH 24TH, 1923.

## THE MECHANISM OF ASTHMA.

WITH the recent advances of knowledge in biochemistry, serology, and anaphylaxis, the vegetative nervous system, and the endocrine balance, much discussion has arisen as to the causation and mechanism of asthma and allied conditions. It is important to bear in mind the existence of these allied conditions and to regard asthma as a symptom or mode of reaction to various irritants which in this instance give rise to manifestations in the bronchial tree. The comparison of pyloric spasm, enterospasm, and mucous colitis (or mucous colic) with asthma illustrates the widespread distribution of this reaction.

Forty years ago asthma was grouped with the paroxysmal neuroses, such as migraine and epilepsy, and the conception of asthma as a reflex neurosis long held the field, though for a time at any rate it has been rather driven into the background by the explanation that it is an allergic phenomenon, resembling but not identical with anaphylaxis. That many cases of asthma are of this nature has been convincingly proved by the ingenious observations of Drs. I. C. Walker and Rachemann of Boston, John Freeman, and others; but all cases cannot be brought under this heading. Accordingly, Dr. A. F. Hurst has constructed an exceedingly inclusive definition of asthma. He would have us regard it as the reaction of the over-excitable bronchomotor portion of the vagus nucleus to blood-borne irritants and to peripheral and psychical stimuli, thus including the classical example of the precipitation of an asthmatic paroxysm when a person hypersensitive to roses was made to smell an artificial rose.

In his able address on the problems of asthma<sup>1</sup> Dr. Langdon Brown agreed with Eppinger and Hess that the asthmatic patient is a vagotonic, or the subject of excessive irritability of the vagus and parasympathetic. The normal balance between the sympathetic and the parasympathetic in health may be disturbed, and it has been stated that practically all diseases tend to produce such a disturbance, resulting in either vagotonia or sympatheticonia, and that certain persons have as part of their make-up a preponderance of activity of the parasympathetic (vagotonia) or of the sympathetic. That excessive activity of the parasympathetic is concerned in the production of asthma has been strongly suggested by the remarkable curative action of hypodermic injections of adrenaline, whereby the effect of sympathetic stimulation is produced; but it must be remembered that an asthmatic paroxysm may be relieved by other means, such as morphine injections and amyl nitrite inhalations. Moreover, the argument that a disease is due to absence of the remedy that brings symptomatic relief must not be pressed, though in the case of endocrine extracts it is, of course, specially attractive. As the activity of the sympathetic is bound up with the output of adrenaline, insufficiency of the adrenals, by diminishing the tone of the antagonizing sympathetic, might lead to a relative vagotonia. If this sequence held good the subjects of Addison's disease and of other conditions, such as acute fevers and infections in which the adrenaline content is deficient (T. R. Elliott), should be specially prone to asthma and other manifestations of vagotonia; as this cannot be said to be the case, relative vagotonia

does not appear to be important in the causation of asthma, and the tempting conclusion that asthma is primarily due to adrenal inadequacy cannot be regarded as established.

An absolute vagotonia, whether inborn or acquired, may, however, explain why certain persons only are hypersensitive to foreign proteins or other stimuli known to excite asthmatic attacks. In favour of this underlying irritability of the parasympathetic (vagotonia) appeal might perhaps be made to the well known hereditary character of asthma and to the frequency with which the hypersensitiveness is shown (at first at any rate) to a group of foreign proteins and not to a single one or to the same one as in the parent. This is a difficult subject, and it may be safer at present to rest content with Dr. A. F. Hurst's view that in some cases an irritable vagal centre, in others a toxic idiopathy, and in some again both these factors, must be regarded as responsible. It is certainly attractive to consider that in asthmatic and allied conditions there are two etiological factors: the disposing condition of the soil, such as vagotonia or a hypersensitive state to foreign proteins, on the one hand, and the exciting cause, such as the foreign protein, or a mechanical or psychical stimulus, on the other hand, which would not produce the asthmatic reaction in the absence of the disposing factor. But here again the conditions may be complicated, for the same factor may appear to set up both vagotonia and the paroxysm. Thus, in recording cases of asthma due to appendicitis, Gutmann<sup>2</sup> argues that the irritation of the terminal fibres of the vagus in the fibrotic appendix, on which Masson has described neuromas, sets up vagotonia, and that for the most part the familiar symptoms of appendix dyspepsia are those of vagotonia. In one of his patients, an asthmatic woman aged 38, pressure over the appendix immediately brought on a paroxysm of asthma. This striking event may of course be explained in other ways—for example, by psychical stimulus—but it raises the question whether in bronchitic asthma the local irritation produces vagotonia and the bacterial toxins act as the exciting agents of the paroxysm.

The conception of vagotonia, though it has met with much critical opposition, appears to be gaining ground, and the question arises whether in asthma and allied conditions there is this underlying factor which disposes the victims of the diseases to become hypersensitive to foreign proteins and other stimuli, or whether, in some instances at least, hypersensitiveness is the only factor.

## SUGAR VERSUS ALCOHOL.

It is said that the Chancellor of the Exchequer may have to make a choice between a reduction of the tax on sugar and a remission of the duty on beer. If a decision between these two alternatives should become the subject of a debate in Parliament, medical opinion may be sought or quoted in favour of one or other of these two proposals. For this reason a few words from the physiological standpoint would not be out of place.

We must begin by frankly admitting that the question cannot be settled satisfactorily or adequately on physiological or dietetic grounds alone. There are considerations of expediency, political as well as psychological, which cannot be excluded from the argument. And the habits and tastes of a people are very insistent facts. From the physiological point of view neither alcohol nor sugar can be regarded as essential elements of the human dietary, while from the economic point of view they must be looked upon as luxuries.

In the case of alcohol, whether in the form of wine, spirits, or beer, there is an unrecoverable loss of about 60 per cent. in the energy value of the grain or sugar

<sup>1</sup> BRITISH MEDICAL JOURNAL, 1922, i, 758.

<sup>2</sup> Gutmann: *Presse méd.*, Paris, 1923, xxxi, 72.

from which they are severally derived. Further than this, alcohol has a very restricted field of usefulness as a source of energy in the body economy. The average man is reputed to be capable of making physiological use of no more than a very few ounces of absolute alcohol in the twenty-four hours. Although this is probably not true of the habitual toper who has learnt the art or the vice of metabolizing alcohol in his system, it may reasonably be regarded as representing the capacity of the average temperate person. On the other hand, the aesthetic and anaesthetic qualities of alcoholic beverages, greatly prized by many, cannot be expressed in terms of calories.

If it is difficult to defend on dietetic and economic grounds alone the virtues of beer and other stimulants, it is equally illogical to claim exemption or remission of tax on sugar on the ground that it is an essential or valuable food for children. Infants in arms alone are dependent on sugar as the source of their carbohydrate supply, and they are only dependent on it because their capacity for malting starch or converting it into sugar is at this period of life incompletely developed. Since all forms of carbohydrate must ultimately be converted into sugar before they can be physiologically made use of in the animal system, it is clear that on the grounds of their energy values, starches and other insoluble carbohydrates if they can be digested are quite as valuable as the more expensive sugars, which, as a rule, cost nearly four times as much. It is only quite recently that sugar has become a staple article of diet in temperate climes, and humanity seemed to get on very well without it. Even a hundred years ago its use was extremely restricted, while in mediaeval and ancient days honey was the only form in which it was used.

As compared with starch, sugar has the grave disadvantage of being so readily digested and absorbed that, when taken in excess, it may flood the blood at a rate greater than physiological conditions require, and as such become an embarrassment to the body as a whole. Farinaceous and other forms of insoluble carbohydrate, on the other hand, by reason of their slower rate of hydrolysis and inversion into soluble and mono-saccharide sugars in the alimentary canal, afford a more sustained reinforcement of the blood with the required carbohydrate supplies. Sugar, in fact, is a pleasant condiment but an expensive food, and it may, by reason of its agreeable gustatory qualities, commend itself so greatly to the taste of children as to lead to the serious pathological results due to excessive consumption. On the other hand, sugar has economic, commercial, and gustatory merits in the preservation and flavouring of cooked fruits, as, for instance, in the making of jam. From the dietetic point of view jams and preserves have much to recommend them as foods for children as well as for adults, and this side of the argument must not be overlooked.

If the sorely tried taxpayer is to have some relief from his burdens by reason of some relaxation of sumptuary restrictions, both beer and sugar may have definite claims on the clemency of the Chancellor, but purely from the physiological and dietetic point of view the claims for such exemption can only be maintained with difficulty, and those of one hardly more so than those of the other.

#### PATHOLOGICAL MUSEUM AT THE ANNUAL MEETING.

THE Committee appointed to organize the Pathological Museum in connexion with the Annual Meeting of the British Medical Association at Portsmouth next July proposes to arrange the material under the following heads: (i) Exhibits bearing on discussions and papers to the various Sections; (ii) specimens and illustrations relating to any recent research work; (iii) instruments relating to clinical diagnosis and pathological investigation; (iv) individual specimens of special

interest, or a series illustrating some special subject. It is also proposed to make an effort to gather together a series of exhibits relating to diseases and injuries of blood vessels; illustrations referring to heredity, and to mental and physical deterioration; series of x-ray and other photographs and sketches. The Museum will occupy a central position in the same building as that in which the sectional work is carried on, and will be easy of access. The Committee desires to enlist the co-operation of members intending to take part in the work of the Sections, and will be glad to hear from those who are able to make exhibits. Every care will be taken of specimens, and the contents of the Museum will be insured. It is hoped to make arrangements whereby exhibitors may have an opportunity of demonstrating their specimens. The chairman of the Committee is Dr. J. A. D. Radcliffe, and the honorary secretaries are Drs. M. Aston Key and A. V. Maybury, jun. Communications may be addressed to Dr. Aston Key, 14, Clarendon Road, Southsea, Portsmouth.

#### RECENT ADVANCES IN THE TREATMENT OF LEPROSY.

SIR LEONARD ROGERS read a paper before the Dominions and Colonies and Indian Sections of the Royal Society of Arts on March 16th on recent advances towards the solution of the leprosy problem. After an interesting survey of the history of this disease, he said that the work of the last few years in improving the treatment of leprosy opened up a vast field for research. As early as 1854 the attention of English physicians was drawn to chaulmoogra oil, an old Indian remedy for leprosy and tuberculosis, which Sir David Prain showed to be derived from the seeds of the tree *Taraxiogenos kurzii*. Philippine observers showed that the seeds of various species of *Hydnocarpus* contained the same active principles. The crude oil given by the mouth had a good effect in leprosy, but it could not be taken for long on account of its nauseating properties. A case was reported from Egypt in 1893, of apparent recovery after a five years' course of injections of the oil, and in 1914 Dr. Heiser reported apparent cures of 11 per cent. of a small series of cases in the Philippines treated by this method, which, however, was painful. In 1915 Sir Leonard Rogers showed Dr. Heiser, in Calcutta, a patient who had nearly recovered under large doses of gynecardic acid, the lower melting point fatty acids of chaulmoogra oil. It was subsequently learned that a soluble sodium salt of gynecardic acid, suitable for hypodermic injection, had been made, and that a case in South America had been successfully treated by it. With the help of Dr. Rosa sodium gynecardate was made; administered subcutaneously this proved to be of value in leprosy, although painful. Its suitability for intravenous injection was next ascertained by means of experiments on animals, and Sir Leonard Rogers soon obtained important results in the treatment of leprosy by that method, and after he left India the research was continued by Dr. Muir. During the next three years Sir Leonard Rogers ascertained that soluble preparations from other oils, including those of cod-liver oil and soya bean, were also effective in leprosy, and two others had recently been added by Dr. Muir. The important principle was thus established that the beneficial effects were not limited to chaulmoogra and *hydnocarpus* oils with their peculiar types of unsaturated fatty acids, as had been previously thought, and a wide field of research was thus opened out, which had been extended to the treatment of tuberculosis. Professor Dean and his colleagues in Honolulu confirmed the work and introduced another soluble product, ethyl ester chaulmoograte, which had previously been put on the market as a patent remedy by German chemists, and which could be more simply and rapidly administered intramuscularly than the sodium salts intravenously, although the latter were also sometimes required in resistant cases. By these methods the leprosy bacilli were gradually destroyed within the tissues, and might in time completely disappear so far as microscopic examination showed, together with all outward

signs of the disease. In a few cases steady progress and complete clearing up had been observed after a reaction produced by a few intravenous injections although all treatment was stopped after the reaction appeared; this indicated the production in the system of effective resisting powers. Sir Leonard Rogers expressed his anxiety that exaggerated hopes should not be raised; it was not wise to speak of "curing" leprosy, as great caution was still necessary. Nevertheless, in the largest leper asylum in India, at Purulia, within eighteen months of Dr. Muir's introducing the treatment on a large scale the mortality had been reduced to one-fifth of the former rate, and a very similar result had been obtained in China. The improved treatment had an important influence in simplifying segregation measures, for the greatest obstacle to effective segregation was the difficulty of isolating early cases of leprosy, who continued to form foci for the spread of the disease as long as they had everything to lose and nothing to gain by declaring their disease. Early cases had already come forward in the more curable stages to ask for the new treatment. Sir Leonard Rogers had strongly advocated in India in 1920 the provision of large leper colonies, with ample ground for cultivation, in open areas away from towns, in place of the Government leper asylums, which were prison-like buildings on very limited town areas. The advantages of such colonies were especially great in view of the fact that the injections had to be continued for many months and in some cases for a year or two. On the most conservative estimate the number of lepers in the world must be well over 1,700,000.

#### THE SUPPLY OF ARTIFICIAL LEGS.

THE thorough and sympathetic manner in which the Ministry of Pensions has dealt with the needs of pensioners who lost a leg in the war must surely be a source of pride to the people of this country. We believe that not one of the late belligerents has taken such pains or lavished relatively so much money as has Great Britain in its efforts to make up for the mutilations of its sailors and soldiers. The note published last week (p. 491) gave a brief summary of the rules for the supply of artificial legs, and some indication of the care which has been taken in this matter. Although the wooden legs which were supplied in the earlier years of the war were the very best then obtainable and gave great satisfaction to thousands of men, it soon became evident that in an alloy of aluminium a material existed which was in some respects, and especially in its lightness, superior to wood. At first the high price charged for such limbs, and still more the very small output of which the maker of the only light metal limb then on the market was capable, prohibited their adoption on any large scale; but modifications introduced during the last two years and the increase in the number of firms able to supply approved patterns have enabled the Ministry to issue light metal limbs to all suitable cases, although their cost is still very much greater than that of the best wooden limbs. The issue of these limbs is generally restricted to amputations above the knee, because it has been found that there is not much difference in weight and no difference in principles of control between the best wooden and the metal limbs for amputation below the knee. It is only in special circumstances, therefore, that the Ministry sanctions the issue of the latter. It is somewhat surprising that so few pensioners have availed themselves of the option of having a peg leg as one of the two prostheses to which they are entitled. The simplicity, strength, and lightness of a good peg leg are such obvious advantages in many circumstances that it might have been expected that the peg would have been popular for certain work and for use in the house. But the desire to hide disability is very strong among ex-service men, and the peg is therefore seldom issued. Should these rules come under the notice of civilians of the poorer classes who have lost a leg they must, we fear, excite envy of the ex-service man, for the cost of aluminium limbs is beyond the purses of most hospital Samaritan funds and

similar charities. The civilian may, however, console himself with the reflection that after all a proper wooden leg is a very good second best.

#### ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

Two years ago, primarily with the object of economizing, the Ministry of Health, assisted by the Society of Medical Officers of Health, came to a decision as to the form which the annual report of a medical officer of health should take and also as to the information which should be required by the Ministry. Local authorities were subsequently informed by circular of the conclusions arrived at by the Ministry, and appended to the circular were certain skeleton tables which medical officers of health were required to utilize. Their use in the annual reports for 1921 was very general and was testimony to the care with which they had been compiled. In a few instances slight modifications were made. Dr. E. Lloyd Owen, medical officer of health for the southern division of the Carnarvonshire combined sanitary districts, has modified and amplified the tables of the Ministry and has brought out, through Messrs. Knight and Co., 227, Tooley Street, London, S.E.1, a set of twelve forms under the name of "The Lloyd Owen Skeleton, Tabular, or Questionnaire Scheme of Annual Health Reports." The first table follows very closely that of the Ministry of Health, but includes information as to zymotic mortality and as to tuberculous mortality, but without distinguishing pulmonary from other forms of tuberculosis. The Ministry asks that the number of cases of diseases notified during the year should be arranged under certain age groups, but this is not provided for in Dr. Owen's table. His tabular arrangement of cases of ophthalmia neonatorum is, however, an improvement on that of the Ministry. The information supplied by the Registrar-General with respect to the causes of death distinguishes between males and females, but in Dr. Owen's table no such distinction is made. The remaining forms in Dr. Owen's series serve a useful purpose in reminding medical officers of health of the information they are required to supply, and the table of "Regulated Establishments" is drawn up with great care and exactness. There are many medical officers of health who will find Dr. Owen's skeleton forms extremely useful.

#### DEATH OF WILLIAM PEARSON.

THERE has just died at his home at Waddon, Surrey, in the 83rd year of his age, William Pearson, who served the Royal College of Surgeons, England, as its prosector for almost fifty-eight years. He was a craftsman of the highest skill, and the excellence of the anatomical preparations with which he enriched the museum of the College not only gives his name a permanent place in the records of the museum, but gives him also a prominent place amongst those who have developed anatomical technique in this country. At Michaelmas term in the year 1856, being then a lad of 15, he was engaged to work as an attendant in the museum. Soon after his arrival Sir Richard Owen went from the College of Surgeons to the British Museum, and was succeeded by Quekett, who in 1861 was succeeded by the late Sir William Flower. In 1862 the late Professor J. Pettigrew came from Edinburgh University to assist Flower, and brought with him a very finished and successful method of unravelling and displaying the arrangement of fibres in muscular organs. In young William Pearson he found a most apt pupil who developed the method, and year after year under a succession of conservators and presidents enriched the museum with series upon series of preparations. His success depended as much upon his knowledge of anatomy and comparative anatomy as upon skill of hand. Even in 1914, when he was in his 73rd year, and when failing health led to his retirement on a liberal pension, his cunning showed no sign of decay. Great as was Pearson's craftsmanship, it was his manhood which attracted and held the esteem of the numerous generations of medical men who were brought intimately in contact with him in the

workrooms of the museum and in the examination hall. His native honesty of bearing and of purpose, his broad healthy humanity, won him the esteem of all the thirty-three presidents under whom he served, the members of the successive courts of examiners to whom he ministered, and the thousands of young candidates whom he guided through the ordeals of the examination room. He was the third of a line of Pearsons—grandfather, father, and son—who served in the museum since it was set up in Lincoln's Inn Fields 130 years ago. Thomas the grandfather, Edward the father, and William who has just died, had a united term of service of 153 years. The late Mr. Clinton T. Dent did William Pearson's wide circle of friends a real service when he commissioned Mr. W. Onslow Ford to paint a portrait of the great prosector. That portrait now hangs in the conservator's office.

#### THE MENTAL AFTER-CARE ASSOCIATION.

THE annual meeting of this useful society, which for more than forty years has rendered much needed assistance to poor persons on their convalescence after an attack of insanity, was held on March 16th at Merchant Taylors' Hall, under the presidency of Alderman Sir C. C. Wakefield, Bt., who was supported by the Lord Chancellor, Sir Frederick Willis (chairman of the Board of Control), Sir James Crichton-Browne, M.D., Sir Maurice Craig, M.D., Dr. Percy Smith, and Mr. D. Cawdron (chairman of the L.C.C. Asylums Committee). There was a large audience, but unfortunately the energetic secretary, Miss Vickers, was absent on account of illness. The report for 1922 was presented by Dr. Rayner (chairman of Council), and its adoption moved by the Lord Chancellor, who, after expressing his high appreciation of the work of the association in supplying those who had successfully passed through asylum treatment with sorely needed aid and advice in starting afresh in the world, referred to the measures now under the consideration of the Government to provide greater facilities for the early treatment, uncertificated, of cases of mental disorder considered curable. After-care, which came specially within the scope of this association, was also receiving the Government's attention, and his Lordship hoped that the visiting committees of mental hospitals would be given further and greater powers in that direction. The good work carried on for so many years by the association indeed afforded encouragement for such a course, though officially provided services did not always successfully compete with those of private individuals rendered out of a spirit of charity and kindness. Sir Charles Wakefield stated that the number of cases applying for assistance had been 944 during 1922, against 874 in 1921 and 379 in 1920. Unfortunately contributions had not increased *pari passu*, and it was extremely desirable to relieve the society of the heavy burden which a deficit of £740 in last year's income had entailed. Patients were discharged "recovered" from our mental hospitals at the rate of some 7,000 annually; a considerable number of them would benefit by the kind offices of the association did its funds permit. The adoption of the report, having been seconded by Sir Frederick Willis, who bore testimony to the good work accomplished, was unanimously carried. The approval of the balance sheet was then moved by Sir Maurice Craig, M.D. (honorary treasurer of the association), seconded by Dr. Percy Smith, and agreed to. Sir James Crichton-Browne, M.D., in an eloquent speech, proposed the re-election of officers, and testified to the excellent arrangements made for the rehabilitation into ordinary industrial life of ex-mental patients—many without homes or friends—who, did they not receive such kindly care and assistance as the association's officers gave, would be apt to relapse in the struggle for existence; and special reference was made to the devotion to the ex-patients' interests of the small salaried staff, whose duties were rendered in the most sympathetic spirit. This was seconded by Mr. David Cawdron, and cordially carried. Mr. Ernest Sanger, L.C.C., and Dr. Henry Rayner proposed

a vote of thanks to the President and the various speakers, which was carried by acclamation, and briefly acknowledged by the Lord Chancellor. The offices of the association are at Church House, Dean's Yard, Westminster, S.W.; the secretary is Miss E. D. Vickers, who will gladly supply any desired information as to its work.

#### THE "PROHIBITION" OF EVOLUTION.

MR. RUDYARD KIPLING's story of the village that voted the world was flat, though at first sight pure farce, is, when philosophically considered, a contribution of historical value, illustrating the fact, not peculiar to this age, that there can always be found a certain number of persons to accept any proposition, however absurd, and to defend it the more enthusiastically the more absurd it is. This curious tendency of the human mind troubled the democracies of Greece and the Fathers of the early church, who found that persecution did not arrest the spread of such opinions, but by producing martyrs tended rather to their extension. Nowadays the tables are being turned, and holders of unusual opinions seek to force them on the community by legislation. It appears that in the United States there is a movement to prohibit the teaching of evolution as applied to man. Legislation to this effect has been proposed in certain States, and the Council of the American Association for the Advancement of Science, at its meeting last December at Cambridge, Massachusetts, thought it necessary to adopt formal resolutions on the subject.<sup>1</sup> The first affirmed that no scientific generalization is more strongly supported by thoroughly tested evidences than that of organic evolution; the second that the evidences in favour of the evolution of man are sufficient to convince every scientist of note in the world, and that these evidences are increasing in number and importance every year. The third resolution affirmed that "the theory of evolution is one of the most potent of the great influences for good that have thus far entered into human experience; it has promoted the progress of knowledge; it has fostered unprejudiced inquiry, and it has served as an invaluable aid in humanity's search for truth in many fields." Finally the Council expressed its conviction that "any legislation attempting to limit the teaching of any scientific doctrine so well established and so widely accepted by specialists as is the doctrine of evolution would be a profound mistake, which could not fail to injure and retard the advancement of knowledge and of human welfare by denying the freedom of teaching and inquiry which is essential to all progress." It was no doubt the existence of this movement to prohibit the teaching of evolution that induced Dr. W. W. Keen of Philadelphia to take "Science and the Scriptures" as the subject of an address he gave at Crozer Theological Seminary last June. He has now expanded the address into a little book with the title, *I Believe in God and in Evolution*.<sup>2</sup> It is dedicated to "all sincere seekers after truth; who revere the Bible as the Word of God; who revere Nature as the work of God; and who believe that, rightly interpreted, they must surely agree." It is a very clear and spirited account of the evidence for evolution from the embryology and anatomy of man and from the history of mankind.

#### SIR FREDERICK MOTT.

SIR FREDERICK MOTT recently accepted the appointment of honorary director of the pathological laboratories of the Birmingham City Hospitals and lecturer in the University of that city on morbid psychology. He has undertaken to pay frequent visits to Birmingham, where he will have a whole-time assistant director. It is hoped eventually to associate various other mental hospitals in the Midlands with the scheme. The laboratories will be established at first at one of the city hospitals, but the intention is that they shall as soon as possible be transferred to the university buildings, as it is considered very desirable that the staff

<sup>1</sup> The full text of the resolutions was published in *Nature*, March 3rd, 1923, p. 293.

<sup>2</sup> *I Believe in God and in Evolution*. By William W. Keen, M.D. Philadelphia and London: J. B. Lippincott Co. (Cr. 8vo, pp. 102, 1 dol.)

of the psychiatric laboratory shall have the advantage of working side by side with other pathologists. Sir Frederick Mott retires from the office of pathologist to the London county mental hospitals and director of the pathological laboratory on March 31st, and will then cease to be a member of the service of the London County Council. He will, however, continue to act in an advisory capacity at the Maudsley Hospital for a further period of six months. He joined the service of the London County Council in September, 1895. He reached the usual age for retirement four years ago, but for various reasons, chiefly in connexion with the establishment of the Maudsley Hospital, and more recently the setting up of a course of lectures and practical instruction for the Diploma in Psychological Medicine—a proposal in which Sir Frederick Mott took a very active interest, and urged on more than one occasion upon the London County Council—his services have been retained beyond the age limit, greatly to the advantage of the Council's work. He had already won high distinction as a neurologist and pathologist when he was selected for appointment by the Council, as he entered the service at a later age than usual. The Council is proposing, subject to the consent of the Minister of Health, to add six years to his actual term of service for the purpose of computing the superannuation allowance to which he will be entitled on ceasing to be an established officer. The Mental Hospitals Committee has suggested to the Council that the circumstances attending his comparatively late entry into the Council's service constitute a "peculiar professional qualification" which is provided for in assessing pensions under the Asylum Officers' Superannuation Act, 1909. It is also proposed that an honorarium of 250 guineas should be paid him for the services which he will render at the Maudsley Hospital in an advisory capacity from April until October next.

#### THE REGISTRAR-GENERAL'S STATISTICAL REVIEW.

We print this week a letter from Dr. Reginald Dudfield containing a detailed criticism of the new form of the Annual Report of the Registrar-General. Dr. Dudfield's eminence as a medical statistician will ensure close consideration of the technical objections he urges against certain changes that have been made. We have ourselves commented upon some of these, and, without endorsing all Dr. Dudfield's arguments, are disposed to concur with his general conclusions. Dr. Dudfield, however, raises issues of importance to others than the members of the unfortunately small class of expert medical statisticians. He appears to hold that the new plan of publication will diminish the utility of the national records for the purposes of the medical officer of health, and in particular refers to the delay which has occurred in publication of the notification statistics. It is possible that Dr. Dudfield is too optimistic in his tacit assumption that other medical officers of health make as good use of the Registrar-General's publications as he does himself. If he is not, we anticipate that his colleagues will also express their opinions upon the expediency of the changes to which he directs attention.

#### THE SCHOOL OF HYGIENE.

We referred last week to the preliminary steps that were being taken to provide that the Imperial School of Hygiene, to be erected in London, shall be organized in a manner worthy of the munificent gift of the Rockefeller Foundation. We then mentioned the further act of generosity on the part of the Rockefeller Trustees which will make it possible to appoint a director of the school at an early date, so that he may be able to superintend its building and equipment, and, as we venture to hope, be afforded opportunities of conferring with his future colleagues. The Ministry of Health now announces that the amount the Foundation has undertaken to provide towards the expenses the director must incur and

towards his salary is £4,000 a year. The steps that should at once be taken have been discussed between representatives of the Ministry of Health, the University of London, and the Rockefeller Foundation, and it has been decided to set up a transitional executive committee to arrange for co-ordination with other bodies already at work in the same or similar spheres. The names of the members of this committee have not yet been announced. A site for the new college has been acquired in Bloomsbury adjoining the area allotted to the University of London, and it is expected that the building for the college may be ready in about two years. Meanwhile the director will act in an advisory capacity to the transitional executive committee. We propose in an early issue to recur to this matter, which must have a very important direct bearing on the teaching of public health and the investigation of the sciences upon which it depends, and indirectly, we may hope, will react upon the unfortunate position in which post-graduate medical education in London appears to be at the present time.

#### IRISH MEDICAL SCHOOLS' AND GRADUATES' ASSOCIATION.

THE forty-fifth annual general meeting of this society was held on March 17th (St. Patrick's Day) at Pagan's Restaurant, when Dr. J. A. Macdonald resigned the Presidential Chair to Sir William Taylor, Regius Professor of Surgery, Dublin University. The report for the past year states that the usual three gatherings had been exceptionally well attended, the numbers at the luncheon during the Glasgow meeting of the British Medical Association being a "record." The winter gathering in London last November took place, in accordance with the new rule, during the week of the General Medical Council meeting in London and afforded thus an opportunity for Irish representatives on that Council to meet old friends and pupils practising in England. The Council expressed the great regret caused by the deaths of Sir Charles Ryall, Colonel Talbot Beamish, and its late honorary secretary, Dr. Walter J. Ronan. Death had also deprived them of one of the few remaining foundation members, Dr. J. Shaw Lytle, formerly of Pontypridd. The Arnott Memorial Gold Medal for this year has been awarded to Dr. Gordon M. Holmes. The festival dinner took place after the meeting, the President occupying the chair, and was attended by 169 members and their friends. After the loyal toasts had been honoured the toast of "Our Defenders" was proposed by the President-elect, Dr. W. J. Corbett, and responded to by Colonel George A. Moore. The toast of "Our Guests" was given by the Chairman of the Council (Dr. Gubbins Fitzgerald), and that of "The President" by Dr. William Hill. Sir William Taylor, in his reply, said the society was showing, by the harmony that existed between those Irishmen and Irishwomen who held such different views both as regards politics and creeds, that the *mens medica* smoothed away obstacles to camaraderie even in Ireland.

#### THE CENTENARY OF THE "LANCET."

THE *Lancet* concludes the hundredth year of its existence in October next, and it is proposed to hold a dinner in celebration of the event. The movement has received the support of Sir Charles Sherrington (President of the Royal Society), Sir Donald MacAlister (President of the General Medical Council), Sir Humphry Rolleston (President of the Royal College of Physicians of London), Sir Anthony Bowlby (President of the Royal College of Surgeons of England), Sir George Newman (Chief Medical Officer, Ministry of Health), Sir William Hale-White (President of the Royal Society of Medicine), and Lord Dawson of Penn (President of the Medical Society of London). The dinner will be held in London in the late autumn. Dr. J. H. W. Laing and Mr. H. D. Gillies, 7, Portland Place, London, W.1, are acting as honorary secretaries.

## MEDICAL SOCIETY OF LONDON.

THE one hundred and fiftieth anniversary of the Medical Society of London, founded by Lettsom in 1773, will be celebrated on May 15th by a dinner to be held at the Hyde Park Hotel. His Royal Highness the Prince of Wales has graciously signified his intention of being present. A gathering widely representative of the medical profession is expected, and there will be distinguished guests. Lord Dawson of Penn, President of the Society, will preside. The Medical Society of London is the oldest medical society in England. Scotland can boast of an older—the Royal Medical Society, Edinburgh, founded in 1737.

Dr. JOHN S. ANDERSON has been appointed to the Chair of Medicine at the University of Hong Kong. Dr. Anderson had a distinguished career at Glasgow University, and during the war served in Gallipoli, Egypt, and Palestine. Later he joined the staff of the Helminthological Department of the London School of Tropical Medicine and became a member of the Commission which visited British Guiana and the West Indies in 1921.

## Medical Notes in Parliament.

(FROM OUR PARLIAMENTARY CORRESPONDENT.)

## Dangerous Drugs Act, 1920.

DR. CHAPPLE, at the end of ordinary questions on March 19th, raised a point of order which appeared to him to be of considerable importance, involving, as it did, an encroachment upon the rights and privileges of the House. The late Home Secretary issued a draft regulation amending the Dangerous Drugs Act of 1920. He issued it on August 3rd last, and the forty days under the Rules Publication Act expired on September 12th. That regulation had had practically the force of law ever since, so that nearly six months had elapsed, during which time a regulation issued by the Home Secretary on August 3rd had practically had the force of law. Section 5 of the Rules issued under the Dangerous Drugs Act, 1920, was to the effect that no practitioner could prescribe for himself any drugs mentioned in the Schedule, such as cocaine and morphine. Section 11 of the Dangerous Drugs Act required that any regulations under that Act should be laid forthwith, but this regulation was not laid until March 1st. Therefore a law had been practically made by the Department and had not been ratified by the House. It ought to have been laid on September 12th last, but it was not laid until March 1st. He asked whether that was not an irregularity, and whether the regulations ought not to be withdrawn. At present it appeared that the Home Department could issue regulations and allow any time whatever to elapse during which time the regulations had the validity of law. Was that an irregularity with which Mr. Speaker could deal?

Dr. Molson associated himself with what Dr. Chapple said. The British Medical Association protested last July against this regulation. The regulation had been carried into force without the consent, authority, or knowledge of the House. It limited the power of duly qualified medical practitioners to prescribe for themselves. He considered that that had been done in an irregular way.

The Speaker replied that it was not for him to say whether the action of the Department had been legal or not. This did not appear to him to be a point of order, but a point of law. If any irregular action had been taken by the Ministry, then he imagined that any honourable member, or anyone who had been harmed by such action, had the courts of law open to him. If the regulations were laid on a certain date—he thought it was February 2nd—

Dr. Chapple remarked that the regulations were promulgated on October 2nd last.

The Speaker said they were laid during the present session of Parliament, and the number of days, so far as he was concerned, dated from that time. What happened in the interval might be a legal question, but it was not a point of order upon which he could express an opinion.

## Army Medical Services.

We published last week (p. 482) the passages in the Memorandum of the Secretary for War which dealt with the Army Medical Services. In the course of the debate on the Estimates, on March 15th, Dr. F. E. Fremantle expressed his

gratification that there was an increase, though only slight, in the provision for the Army Dental Corps. Medical officers who had served during the war knew how vital dental work was and how fruitful a source of invaliding and inefficiency was the absence of proper dentistry. Very frequently insufficient provision for the dental condition of the troops, and the recruit in the first instance, resulted in the loss of enormous sums of money, due to the fact that they had to be invalided through troubles of digestion and nutrition which arose through defective teeth. It had been difficult to get a sufficient number of dental surgeons during the war, because qualified dental surgeons were not numerous. When it was decided, as a new departure in the permanent army, to have a certain establishment of dental surgeons, those who had served so well were encouraged to join permanently; eighty-three did join, but the gratuity promised to them when they left the service was withheld if they entered the permanent service. The British Dental Association had appealed to the War Office, but the Army Council had repudiated the agreement made under Instruction 131. Turning then to the problem of the Army Medical Corps of the Territorial Army, Dr. Fremantle said that the original idea was that in all the reductions the cadre of all the different units should be kept up, so that in the event of war—as in the case of the late war, thanks to the scheme initiated by Lord Haldane—there could be complete expansion. One of the chief requirements for expansion was the availability of big general hospitals. As regards the ordinary technical medical and surgical work, the general hospital could in war obtain the necessary staff from civil practitioners. The real requirement was the military organization of the hospital to make the organization work smoothly. The establishments should be kept up in peace time in such a way that they might be able to get to work at once. The nucleus of the Territorial Army medical units was the general hospital. These units had been cut down. Instead of fourteen Territorial general hospitals, there were now only three—one in London, one in Edinburgh, and one in Manchester. It would be infinitely better to have the cadres of ten big general hospitals in the big centres in order that a fresh set of medical officers might have training in the organization and running of a hospital. There was something wrong in regard to the Royal Army Medical Corps. Since the South African war it had held a very high position; in fact, among the medical services of the Crown it had attained to the premier position. But when the last examination was held for fifteen vacancies in the corps, there were only four applicants, and only three passed the test. All four were, however, given commissions, and the remaining eleven commissions were left vacant. He could not understand the falling off in the popularity of the corps; but he imagined that some of the conditions did not correspond sufficiently well with the prospects in civil life, and that that was one of the results of economy. He favoured economy, but the Army Medical Corps must be saved. The man who was responsible for the whole of medical service and that connected with the health side of the army work should have a seat on the Army Council. The Escher Committee declined to recommend this, its objection being that the Army Council was already large enough. But, as a result of the war, Lord Escher had reversed his opinion. In conclusion, Dr. Fremantle touched on the question how far the co-ordination of the services (the Army, the Navy, and the Air Force) would affect their Medical Services. The Cabinet Committee, under, he believed, the chairmanship of Sir Alfred Mond, did report, as he understood, last summer, on this subject. But when he asked if the report would be published he received no reply. He pressed this question again, because the publication would be of great value. He allowed that possibly the fusion of the Medical Services could not be affected very much in advance of the general fusion of all the fighting forces, but it was bound to come, and the sooner the better.

Lieut.-Colonel Guinness (Under Secretary of State for War), replying to the discussion, said his answer to the appeal that the Director-General Army Medical Service should be a member of the Army Council was that members of the Army Council had never sat as representatives of particular groups or kinds of soldiers. They sat as representing groups of functions. It was true that there were instances in the War Office organization which seemed to support the opposite principle, such as the Director of Supplies and Transport, the Director of Engineering, the Master-General of the Ordnance, who were each of them virtually commandants of certain corps and administered the personnel. If representation was to be given on the Council to the Territorial Army, as one M.P. had suggested, and to the Royal Army Medical Corps, as Dr. Fremantle had urged, the same claim would soon be made for the Royal Engineers.

Dr. Fremantle (interposing) said that was just the mistake which was constantly being made and against which he contended. He desired that the Director-General

of the Royal Army Medical Corps should be on the Council to represent the health services which functioned throughout the army. The Director-General was responsible for the whole of the health services in all parts of the army administration.

Lieut.-Colonel Guinness said he quite realized that a good many people held the view just expressed, but he suggested that all these matters could best be considered by such a committee as that under the chairmanship of Lord Weir, which was going into the whole of the establishment and the organization which controlled it.

#### Nurses' Registration Act.

Major Barnett, on March 14th, moved for an address to His Majesty for the modification of the Schedule to the Nurses' Registration Act, 1919, for the election of the General Nursing Council for England and Wales. He submitted proposals for some forty amendments to the scheme, but said that there were only three of substance. The first dealt with the qualification of the people who should represent the registered nurses on the Council. In the debates in the House on nurses' registration two points received great stress. One was that nurses should be raised to the status of a profession, and the second that they should be independent in the choice of their representatives. The matrons were a very distinguished body of women, and he did not wish to deprive them of the privilege of being elected members of the General Nursing Council. But under the scheme it was laid down that six of the eleven representatives of the registered nurses should be past or present matrons. The amendment he put forward was that the registered nurses should elect eleven nurses to represent them, and that they might be matrons or not. This followed a precedent set in Scotland. The second point was to make the time between the date of the dispatch of the voting papers and polling day twenty-one days instead of seven. The other amendment dealt with the powers of the returning officer, who, under the rules, was able to sit in judgement on his own mistakes.

Mr. Neville Chamberlain, in reply, said that during the short time he had been in office it had been impossible for him to make adequate investigation into this matter. But if the motion were withdrawn he would undertake to request the General Nursing Council to consider the amendments put forward, and to draw up and submit to him such alterations as the Council might be prepared to make within the next twelve months. These alterations, if approved by him, would be laid on the table and open to discussion. Major Barnett expressed his willingness, in the circumstances, to withdraw the motion.

**Small-pox in London.**—Mr. Rhys Davies asked, on March 14th, whether during the recent small-pox "scare" in London any intimation was sent to medical officers of health on the subject of closing of business premises in the event of small-pox occurring thereon. Mr. Chamberlain replied that the only communication traceable was a statement in answer to an inquiry by a firm of solicitors that the Department was not aware of any statute or regulation empowering the Minister of Health to order the closing of a factory wherein cases of small-pox had occurred. The question whether it was or was not desirable to advise the closing of a factory on account of the occurrence of cases of small-pox rested with the medical officer of health of the district. In reply to Mr. Frank Lee Mr. Chamberlain said that the medical officers of the Ministry who advised in regard to the diagnosis of suspected cases of small-pox were those who had considerable experience of that disease, and in forming an opinion as to the nature of the illness they took into account all known factors, including the vaccinal condition of the patient. Mr. Frank Lee desired information as to the report of the Departmental official who made an investigation in Derbyshire. Mr. Chamberlain said that such reports were intended to be confidential, and he did not propose to publish the reports made by medical officers of the Department as to this outbreak. He was advised that the isolation of contacts was not generally necessary either in the interest of the contact or for the protection of the public unless or until the contact developed the disease. Mr. Spencer asked whether the reports were available to the council or councils interested. Mr. Chamberlain said that they were not; the reports were confidential to the Department.

**Maximum Size of Panels.**—Mr. Chamberlain informed Mr. Burgess, on March 14th, that while the maximum number of patients for whom an insurance practitioner working single-handed might accept responsibility was 3,000, the Insurance and Panel Committees had power to fix a lower number as the limit for that particular area or for any portion of it. The extent to which the number might be increased in a case of a practitioner employing a permanent assistant was a matter within the discretion of the local committee. The information available indicated that in general the employment of an assistant was held to justify the increase of the number by about 50 per cent. Mr. Pringle observed that the numbers given were not of patients but only of potential patients; there was only a small number of actual patients in the total.

**Medicines for Panel Patients.**—Sir W. Sugden asked, on March 14th, what steps were being taken to ensure fit and proper medicines being supplied to panel patients where the price of such medicines was higher than the sums allowed in the contract. Mr. Chamberlain replied that the cost of medicines for insured persons was not subject to any such limit as was suggested. Insurance practitioners were required to order for their patients such medicines

as were necessary for their proper treatment without limit of price, though it had been found necessary to take certain precautions against extravagance in prescribing. Mr. R. Richardson asked, on the same day, if the Medical Subcommittee of the Durham County Insurance Committee had recently fined medical practitioners on the panel for alleged excess in the cost of drugs given to panel patients, asserting that drugs of a less expensive character should have been given and that medicine should have been ordered to have been given at greater intervals; and whether the Minister of Health would have inquiries made into this with a view to the proper treatment of persons suffering from ill health. Mr. Chamberlain replied that the withholding of remuneration on the ground of excessive prescribing was settled by the Insurance Committee, which received independent advice from the Panel Committee. He had not yet received the reports of the particular cases to which Mr. Richardson referred, but he had no jurisdiction to review the Insurance Committee's decisions unless the doctors concerned exercised their right of appeal to him. There must be some safeguard against extravagance in prescribing, but the present arrangements were not working well and were under revision.

**Pensions Administration Cost.**—In a written answer to Sir John Collier, on March 9th, Major Tryon stated that the estimated total cost of administration of the Pensions Department (including committees) for the financial year ending March 31st was £4,180,000, of which £1,110,000 was for medical services. The cost of sessional fees for boarding during the current financial year was estimated at £450,000. Salaries of medical officers could not be readily apportioned as between boarding and treatment duties. The number of whole-time medical officers employed on August 1st, 1921, and on February 1st, 1922, were 623 and 605 respectively. Of these, 315 and 289 were employed in institutions. The number of medical boards of any kind varied from day to day, according to requirements, but the average number of three-men boards was about 170 a day. All cases coming up for resurvey were now examined by two-men boards.

**Death Certification.**—At the instance of Mr. Snell, on March 14th, Mr. Chamberlain gave the following particulars of the registration of deaths during the last five years:

#### Deaths Registered.

	On Medical Certificate.	On Coroner's Certificate.	Uncertified.	Total.
1918	570,735	33,012	8,214	611,961
1919	466,068	31,483	6,698	504,249
1920	429,456	31,611	5,653	466,720
1921	424,166	29,301	5,240	458,707
1922	450,996	30,346	5,487	486,829

**Houses Unfit for Habitation.**—Mr. Neville Chamberlain stated, on March 14th, that reports received from medical officers of health for 1,050 boroughs and urban districts for the year 1921 showed that 994,005 houses were inspected under the Public Health Acts and Housing (Inspection of Districts) Regulations. Of these, 13,279 were reported unfit for habitation and 226,713 not in all respects reasonably fit. Notices were served under the Housing Act of 1919 in respect of 30,815 houses, and of these 23,453 were remedied by the owners and 912 by the local authorities. Notices were served under the Public Health Acts in respect of 266,549 houses; in 240,310 of the houses concerned the defects were remedied by the owners and in 2,757 by the local authorities. Closing orders were made in respect of 1,416 houses, while in the case of 287 houses closing orders were ended after the houses had been made fit. There was no information as to the population inhabiting these houses.

#### Answers in Brief.

Major Tryon has stated that there are approximately 830 service patients in the mental hospitals of the London County Council. Payment for the cost of their maintenance and treatment was made by the Pensions Ministry direct to the medical superintendents of the hospitals. During treatment pension was suspended and the allowances authorized by Article 6 of the Royal Warrant were granted.

The difference between the number of State-assisted houses completed up to February 1st and the gross estimate of shortage due to overcrowding according to the survey was 312,595. Information is not available as to the number of unsubsidized houses built since 1919, and the figures given are not to be taken as giving the present effective demand for houses.

The Home Secretary has stated that the alleged increase of drunkenness from the consumption of methylated spirits has been under the consideration of the Home Office for some years, but it was not a matter in which he had any powers. He understood that it had not been found practicable to make the spirit more unpalatable.

Mr. Chamberlain has informed Mr. Hayday that the work of public vaccinators was periodically inspected by medical officers of the Ministry of Health. The Royal Commission on Vaccination had said, as regards the protection afforded, that though in all cases it was not the same, if a period was to be fixed, they thought it might fairly be said to cover in general nine or ten years.

Regulations to prescribe standards and labelling for imported condensed milk have been prepared by the Ministry of Health, and notice of intention to make them, subject to the consideration of representation by any public body interested, has been given in the *London Gazette*.

## Nova et Vetera.

### A TIBETAN ANATOMICAL CHART.

Among the trophies of the second Mount Everest expedition is an anatomical chart brought back by Captain J. B. L. Noel from a Tibetan monastery at Gyantse, in the mountainous regions between Darjeeling and Lhasa. Captain Noel was the official photographer to the party, and his wonderful cinematograph films have been shown in London and more recently in the large cities of Scotland and the North of England. We are indebted to him and the Mount Everest Committee for the opportunity to reproduce a photograph of this chart in our columns.

Picture-scrolls, or *tankas*, are common features of the monasteries of Tibet; they are either hung on the walls or kept rolled up in pigeon-holes. This one is painted in water colours on some kind of prepared canvas, and has evidently been rolled up for a long time, for its outermost surface is much discoloured; it measures some 24 inches by 16 inches. The drawings are enclosed in a gay red and yellow border; the anatomical figures are coloured diagrammatically, red and pink predominating; the background is lightly washed in with blue above and green below. Dr. A. F. R. Wollaston, who was medical officer and naturalist to the first Mount Everest expedition in 1921, informs us that he saw several anatomical charts like this in Tibet, but none so complete. It has been examined by Dr. Frederick W. Thomas, Librarian to the India Office, whose knowledge of Tibet and its language has helped us greatly in compiling this note.

The writing on the picture is in a neat cursive form of the Tibetan script adopted from the Hindus in the seventh century A.D. The letters are thus akin to the Indian Sanscrit characters of that period, and therefore read from left to right. The letters of the running script differ from those of the formal, or sacred, script in being "unheaded" and less ornamental.

In general Tibetan medicine, like Tibetan writing, is based on the Hindu, with perhaps some admixture of Chinese. The legend at the foot of this picture informs the reader that the chart illustrates a chapter from the well known medical treatise called *Vaidurya-si-on-pohi-phreng-ba* (The blue beryl necklace, or String of blue jewels). The *Vaidurya* appears to be a commentary on the four medical authoritative texts, or *tantras*, ascribed to Buddha in his capacity as the great physician. The particulars filed by Dr. Thomas in the library of the India Office show the *Vaidurya* to be a large and exhaustive work of 1,000 leaves, each printed on both sides, the whole forming a complete system of the science and art of medicine.

There is no clue to the age of the picture; it may be anything from 50 to 300 years old. The anatomical details are crude and fanciful; they are indeed rendered with a spirited

disdain for accuracy; they bear out Garrison's observation that Hindu medicine was particularly weak in its anatomy. Like the pre-Vesalian anatomical drawings of Europe, this Tibetan chart bears little evidence of original observation or dissection. It has rather the appearance of being the work of a skilled copyist working to a traditional pattern and adding such artistic flourishes as his fancy directs. "These strange didactic pictures have all been interpreted by Sudhoff as side-lights on the almost stationary character of the mediaeval mind."\*

According to the key lettering the mountainous object in the top left-hand corner represents the lungs and heart; and this conventional rendering is repeated in the thorax of the

squatting figure below. The upright skull-faced figure is flanked by a small liver with a large gall bladder (this is painted yellow) showing beneath its lower border, and another larger gall bladder detached from its surroundings. In the upper squatting figure the intestines are shown in two zones labelled upper and lower, and the crura of the diaphragm are indicated. In the posterior view of the upright figure the kidneys are turned outwards and shown in section, their sites being indicated in the flanks; above the left kidney appears an isolated spleen, which is coloured mauve in the original. It will be noted that the patella appears in both the front view and the back view, and the spinal column is represented as consisting of twenty-seven pebble-shaped vertebrae. The coiled object in the centre of the picture to the left of the middle line is intended to represent the stomach and intestines. In each of the central squatting figures the thorax is decorated with a great deal of information.

We learn from Mr. C. J. S. Thompson, Curator of the Wellcome Historical Medical Museum, that that collection possesses several coloured drawings, reproduced from a Tibetan manuscript, depicting anatomical subjects. The original scroll, ascribed to the fifteenth century, is preserved at the Bibliothèque Nationale in Paris.

Some account of the anatomical knowledge and medical practice of Tibet has been given by Dr. Heinrich Laufer in his *Beiträge zur Kenntniss der tibetischen Medizin* (Leipzig, 1900), and in another pamphlet published in the same year at Berlin. Lieutenant-Colonel L. Austine Waddell, I.M.S.(ret.), formerly professor of Tibetan at University College, London, in his work *The Buddhism of Tibet*, speaks of the very popular form of Buddha representing the god as "the supreme physician" or Buddhist Aesculapius; this, he says, was probably founded upon the legend of the metaphysical Bodhisat, "the medicine king." Aesculapic pictures or medical Buddhas are much worshipped in Tibet, and are supposed to cure by sympathetic magic. This circumstance may account for the squatting Buddha-like attitude of four out of the six figures in the anatomical chart.

## England and Wales.

### LIVERPOOL MEDICAL INSTITUTION.

A SPECIAL general meeting was held on March 13th to receive the report of the Revision of Laws Committee which had been accepted and approved by the Council. The President, Dr. J. Hill Abram, occupied the chair, and there was a moderate attendance of members. An interesting discussion centred around the use of the word "institution" representing the corporate assembly of members and the building in which they met. This twofold signification gave rise to excursions into the history of the medical profession in Liverpool, the etymology of the word "institution," and the various meanings attached to the word by the *New Oxford Dictionary*. It has been ascertained that the first association of medical men in Liverpool had for its object the formation of a medical library. In 1779 out of this Medical Library Society arose a society called the Liverpool Medical Society, and, as far as the records go, this society was the most important at that period. In 1837, through the untiring efforts of Dr. John Rutter, the Liverpool Medical Institution was erected with the express object of housing the library, the pathological museum, and providing a place for medical men to meet and discuss matters of medical interest. Up to 1840 the word "institution" was used solely to designate the building, and chosen in preference to the word "hall." Owing to friction between the trustees of the building and the associations that used it, an arrangement was made whereby the building was taken over by the united associations, of which the Liverpool Medical Library Society was the most important. It was then the word "institution" received its second meaning, and, incidentally, the term "Liverpool Medical Society" passed into oblivion. It was felt by those who knew and had studied the past medical history that the phrase "Medical Society of Liverpool" might be with advantage substituted and thus preserve the continuity from 1779 down to the present. In so doing, the word "institution" would be confined to its original designation, and the corporate body of members meeting within its precincts be styled the Medical Society of Liverpool. The majority of the members present were averse from change and determined to continue the use of the word "institution" in its twofold signification, leaving the context of the laws to reveal which meaning was the correct one. A new law referring to life members was unanimously adopted. Its object is to free from subscription any associate or member who has completed fifty years of membership of the institution. The clause referring to the ineligibility of persons practising homoeopathy or of those who assume any designation implying special principles or methods in the practice of their profession was unanimously deleted. It was felt that the method of electing members was in itself sufficient to safeguard the objects of the institution.

### BIRMINGHAM GENERAL HOSPITAL.

The board of the General Hospital, Birmingham, in consonance with other large hospitals throughout the country, has instituted an Extern Midwifery Department. For those who know the location of the hospital the wisdom of this step will be obvious; for those who do not, it may be said that the hospital is situated on the edge of a very impoverished district, where confinements are necessarily fraught with great risks to mother and child. The limits of the "district" to be served by the new department have been fixed to extend to a radius of a mile and a half from the institution. This will include the worst slum area in the Midlands, and it is felt by the board of the hospital that much good work can be done amongst the overcrowded population it harbours without in any way prejudicing the interests of other bodies or individuals. The department is under the direct control of the honorary obstetric staff of the hospital, under whom are the obstetric house-surgeon, a specially trained sister, and certain nurses—specially selected by the *matron*—who have completed their full course of general training. To secure the services of the department the patient applies to the registration office of the hospital and pays a nominal registration fee of 15s. This figure is much lower than the fee it would be necessary to pay, in the ordinary way, to engage competent attendance at the confinement, and should be within the scope of many who have hitherto had to rely on unskilled assistance. Not only this: the fee is comprehensive, entitling the patient to

treatment for all complications arising out of pregnancy from the day of registration. Thus a case of too great difficulty to be managed at home would be taken into the hospital, where the confinement could be conducted under safe conditions. Registration early in pregnancy will be encouraged so that ante-natal treatment may be given whenever necessary; it is the aim of the hospital to develop this aspect of the scheme to its fullest extent. In spite of the modesty of the registration fee it is calculated that it should cover the working expenses of the department. During the past decade great advances have been made in private obstetric work, and the certificated midwife of to-day is, as a rule, very competent. Pregnant women also are becoming more aware of the risks associated with their condition, and the grave menace of incompetent help during labour. Thus a favourable reaction is set up which makes for better service. But improvements of this kind do not lessen the cost to the patient, and to the class of people inhabiting the slum covered by this scheme the new Extern Midwifery Department should prove to be of incalculable benefit.

### POST-GRADUATE LECTURES AT BIRMINGHAM ON CRIME AND MENTAL DEFECT.

The Faculty of Medicine of the University of Birmingham has arranged another course of post-graduate lectures and demonstrations on crime and punishment. The course will begin on May 7th and end on May 19th. The lecturers will be Dr. W. A. Potts, who will treat of the subject with special reference to mental defect; Dr. Percy Hughes, who will consider it in relation to insanity; and Dr. Hamblin Smith, who will deal with the subject generally. There will be demonstrations at the Barnsley Hall Asylum by Dr. Percy Hughes, at the Mental Deficiency Office and Barr Hall Colony by Dr. Potts, and at H.M. Prison by Dr. Hamblin Smith. The fee for the course is five guineas. Full particulars can be obtained from the Dean of the Medical Faculty, Mr. W. F. Haslam, F.R.C.S., the University, Edmund Street, Birmingham. As will be seen from the advertisement on another page, the course will not be held unless sufficient entries are received.

### POOR LAW OFFICERS' REMUNERATION.

The Minister of Health has issued a Circular (382 of March 15th, 1923) to Poor Law authorities dealing with the procedure to be adopted for obtaining the Minister's approval of the remuneration of Poor Law officers. In Circular 223 of 1921 it was laid down that, in the absence of any proposal for an increase in salary, no statement of expenditure need be submitted to the Minister. The present circular emphasizes the fact that the approval of the Minister is no longer required for the appointment of Poor Law officers, unless the proposed remuneration exceeds that already sanctioned for the previous holder of the office, or the person proposed to be appointed lacks one of the qualifications prescribed by the regulations or (in the case of a whole-time office) has had no previous experience in the Poor Law service.

The circular contains no new provision. Its chief interest lies in the following explicit statement of the existing position as regards the security of tenure of Poor Law officers, necessitated, presumably, by the attitude adopted recently by certain authorities with regard to retrenchment:

"... Nothing in this procedure will affect an officer's security of tenure or other conditions of service prescribed either by the Regulations or by the terms of his appointment. It will not, for example, be competent for the authority to dismiss without the consent of the Minister an officer entitled under the Regulations to permanency of tenure. When a salary within the approved limits has been assigned to an officer by a resolution of the authority, it will not be competent for them to reduce such salary without his consent during his legal continuance in office."

### THE WILLIAM SHEPHERD HOSPITAL BEQUESTS.

The late Mr. William Shepherd, a builder and large property owner in the City of London, left the residue of his estate to be distributed to London hospitals by his executors; having realized a portion of the estate they have now distributed £96,500 as follows:

£35,000 to Guy's Hospital to finance the erection and completion of the new to be name use." the erection and completion of a w ator.  
£20,000 to St. Thomas's Hospital for the erection of dining and recreation rooms for nurses in the hospital, the new building having a flat roof to provide a playground for children patients in the wards.

£6,000 to the Belgrave Hospital for Children, for the purpose of continuing the erection and completion of the south wing, which will provide two large additional wards, together with extra accommodation for nurses on the upper floors.

Sums of £1,000 have been apportioned to the following London hospitals for the endowment of beds to perpetuate the memory of the testator: The City of London Hospital for Diseases of the Chest, the Middlesex Hospital, the Hampstead Hospital, Charing Cross Hospital, St. Mary's Hospital, St. George's Hospital, the Evelina Hospital for Children, the Miller General Hospital, the Royal Free Hospital, the Westminster Hospital.

In addition, the sum of £500 has been given to the St. Monica's Hospital.

Mr. H. P. Shepherd, C.C., the testator's son, and one of the executors, has in many cases been appointed a governor of the hospitals to which help has been granted.

## Scotland.

### A "MAINTENANCE SYSTEM" FOR SCOTTISH HOSPITALS.

SIR GEORGE BEATSON'S pamphlet, *The Scottish Voluntary Hospitals*,<sup>1</sup> is an interesting exposition of a financial proposal for relieving the difficulties of voluntary hospitals, called the "maintenance system" of finance. Sir George regards the abbreviated expression "voluntary hospital" as indicating a hospital that is supported by voluntary contributions, and considers that the definition embodies the elements of gratuitous support and service. These hospitals, he says, are indirectly an outcome of the Poor Laws. The Act of 1601 directed that provision should be made for the sick poor. The management of the infirmaries established and the care bestowed on the sick poor were so lacking in humanity that great public resentment was created; and the growth of human compassion in the eighteenth century led to the establishment of many voluntary hospitals for the necessitous sick poor.

Times, however, have changed. A humanitarian spirit has permeated the official world; Poor Law hospitals have now all that can be desired in the way of equipment, comfort, and skilled treatment, and the voluntary hospitals are now providing for the needs of sections of the community other than the necessitous sick poor. But the managers of voluntary hospitals are trying to meet the increased expenditure due to modern methods of treatment by collecting money for the deserving poor while utilizing the money so collected in giving what is practically indiscriminate charity to members of the community, many of whom are able to pay for treatment. Through these changes an embarrassed position has been brought about in voluntary hospital finance; and this position must be met by a change in the financial arrangements, since voluntary hospitals must be continued for two reasons—first, because they perform a widespread social service, and secondly, because they carry on a great educational work which benefits all classes of society.

Sir George Beatson is of opinion that the following requirements should be met by any new financial system:

1. It should allow for contributions being made by all classes of the community, as all are benefited by the voluntary hospitals.
2. It should continue the present excellent system of voluntary service by the medical staff, unpaid.
3. It should bring in an assured income without the hospital having to depend on recurrent appeals.
4. It should carry with it an element of permanency.
5. It should not open the door for interference with the control of the hospitals, as by any special body of contributors.

He considers that these requirements would be met under an arrangement by which the maintenance of the hospital itself (management, buildings, rent, taxes, salaries, wages, etc.) would be borne by the general public, through charitable gifts, legacies, and so on, while the maintenance of the patients (provisions, drugs, and dressings) would be borne by the patients themselves, either personally or through benefit societies. To this plan he applies the name "Maintenance System."

An analysis is given of the accounts of the Glasgow Royal Infirmary to show that about two-thirds of the annual expenditure is incurred for the maintenance of the hospital itself, and one-third for the maintenance of patients. Sir George Beatson quotes figures to show that in Scotland treatment in hospital for an average of twenty-one days would cost the patient £3 18s. 9d. in surgical cases with operation,

£2 17s. 9d. without operation, and £2 6s. 9d. in medical cases. The hospitals would maintain a certain number of endowed beds for deserving necessitous patients. It is proposed that the maintenance system of finance should be carried out by some scheme of insurance, it being understood that any such insurance must be arranged by the applicants themselves and not by the hospitals, as no hospital should take upon its shoulders the risks of an insurance company. It is suggested that the various "contributory schemes" and the "Hospital Savings Association" should take up this work of insurance, forming themselves into hospital treatment insurance societies, prepared to meet the maintenance charge for their members when in hospital, and abandoning their present propaganda, which seems likely to undermine the voluntary principle in hospitals in various ways. It is recognized that an "income limit" would be necessary for admission, and the hospital authorities would, of course, be the sole judges as to the suitability of a case for treatment in hospital. Sir George Beatson claims the following advantages for the maintenance system of hospital finance:

1. It gives an opportunity for combining public help from charitable subscribers with self-help by the patients themselves, so that all classes will contribute to the support of hospitals, from the existence of which all are benefited.
2. It would do away with the "open-door" principle of admission, and establish relations on a fixed business-like basis between the voluntary hospitals and the working and lower middle classes.
3. It would help to foster thrift, which is distinctly discouraged by the present voluntary hospital system.
4. Under the system there will be no grounds for medical men claiming remuneration for the services they render, because the hospitals will be receiving no payment for treatment. This is qualified in respect of any work carried out for the State or municipality, in which case remuneration for the medical men doing the work would be included in the charges.
5. An assured annual income would be received by the hospital, coming in weekly, monthly, or quarterly as arranged, thus freeing the hospital from embarrassment in meeting its running expenses.
6. The system furnishes no loophole for invasion of, or interference with, the control of the hospital.

Such advantages cannot, Sir George Beatson considers, be claimed for the contributory schemes for employees now being developed, schemes which open the door to "class interference" in the management of hospital affairs, and are not unlikely to lead in the end to State control. Sir George desires that the voluntary hospitals should recognize that their function now is to help a deserving class of the community whose means debar them from obtaining in serious illness modern expensive methods of treatment and nursing, and that the benefits they bestow should be obtainable, except in absolutely necessitous cases, only by those who are prepared to contribute on the principle of self-help.

In his preface Sir George Beatson, who has worked in hospitals for over fifty years, and been on the surgical staff of a hospital with a large medical school for thirty-two years, states, with a touch of dry humour, that he offered to place his views before Lord Cave's Committee, but that the offer was not accepted because only witnesses with experience in hospital matters were desired.

### CHARITY IN MEDICINE AN ANACHRONISM.

At the annual meeting of the Odonto-Chirurgical Society of Scotland, held in Edinburgh, a discussion on "The necessity for co-operation between the different branches of the medical profession" was opened in an address by Dr. J. S. Fraser, F.R.C.S.E. The lecturer held that the hope of progress lay in the co-operation of specialists in the different branches. He held that charity in medicine was an anachronism and that patients should be treated because they were human beings and citizens, not because they were poor. Discussing hospital treatment, he pointed out that the middle classes, especially the lower middle classes, were worse off than anybody else. The wealthy classes could afford to go to numerous West End specialists and obtain the opinion of each one upon their cases, though even this was not ideal, because the patient laid most stress upon the symptoms which he thought would be of most interest to the particular specialist he was visiting. On the other hand, the poorest classes had the general hospital to go to. The lower middle classes fell between two stools, because they could not afford numerous private consultations and did not care to go to charitable hospitals. Probably the best solution of all would be to have only one hospital, a general hospital, with paying wards attached to each department, as in America. In Edinburgh there were far too many little nursing homes which were not economic.

<sup>1</sup> *The Scottish Voluntary Hospitals: A Financial Reconstruction Scheme.* By Sir George Thomas Beatson, M.D., K.C.B., K.B.E., D.L., Consulting Surgeon, Glasgow Western Infirmary. Glasgow: John Smith and Son. (Med. Rev., pp. vi+18. 6d.)

units, but were run under the system of private enterprise. A possible solution of the problem might be the establishment of a local health rate after the analogy of the education rate. For Edinburgh it had been calculated that this might amount to fourpence in the pound of rental, but the lecturer held that this would be only a beginning and that it would rise.

#### LETHARGIC ENCEPHALITIS IN EDINBURGH.

Seven deaths from encephalitis lethargica have occurred in the Edinburgh Royal Infirmary in the past month, and there have been several cases in other hospitals. Of the deaths in Edinburgh, 5 were in men over 40 years of age and 2 in women of 29 and 24 years respectively. Children have been affected, generally speaking, in a milder degree. In most of the cases mental disorder has been the most prominent early symptom, followed later by third and seventh nerve paresis, the lethargy being of later development. The most effective treatment appears to have been some form of vigorous counter-irritation such as turpentine hypodermic injection for the production of an abscess in some indifferent region like the outside of the thigh. This usually produces striking amelioration of the symptoms. It not only causes a marked local reaction with leucocytosis, but presumably relieves the cerebral congestion which is the outstanding morbid anatomical feature of the disease.

#### END OF WINTER SESSION.

The winter session of Anderson College of Medicine, Glasgow, closed formally on March 15th, when an address was delivered by Sir John Bland-Sutton, F.R.C.S., LL.D. The subject of the address was "The choroid plexuses and ventricles of the brain as a secreting organ," and it was listened to with great pleasure by a large audience of students and teachers. The Chairman of Governors of St. Mungo's Medical College, Glasgow, Mr. James Macfarlane, LL.D., presided at the closing meeting of the winter session on March 15th. He referred to the large numbers of students attending the College and to its continued prosperity as a teaching centre. After the various prizes, medals, and certificates had been presented to the successful students, Sir John Reid, K.B.E., gave a short address.

#### REQUESTS FOR CANCER RESEARCH.

Mrs. Constance Armstrong, widow of the late Captain Armstrong of the Royal Mail Steam Packet Company, left the greater part of her fortune to be distributed to hospitals and institutions directly or indirectly assisting sufferers from cancer. The trustees of her estate have allocated £1,600 to the Caird Cancer Wards, Dundee Royal Infirmary, and £1,600 to the Imperial Cancer Research Fund, London.

#### AFTER-CARE OF BLINDED SCOTTISH SOLDIERS.

The annual meeting of blinded Scottish sailors and soldiers, who were trained and are being looked after by St. Dunstan's, took place last week in Edinburgh. Over a hundred of these men are settled in and around Edinburgh engaged in poultry farming, boot repairing, making of mats, baskets, and nets, or as joiners, masseurs, etc. St. Dunstan's provides them with the necessary raw materials for their occupations and assists them in the disposal of the finished articles. Captain Ian Fraser, C.B.E., the blinded officer chairman of St. Dunstan's, in the course of an address to the men, said that the decline since 1919 of the income of St. Dunstan's in common with that of other philanthropic institutions connected with the war was causing considerable anxiety. Nevertheless St. Dunstan's was still going strong, and although it had been severely handicapped in the raising of funds by the loss of Sir Arthur Pearson, he counted on the generosity of the people of the empire to enable them to keep their pledge to the blinded men.

#### EDINBURGH EYE, EAR AND THROAT INFIRMARY.

This institution, with which the Eye Dispensary has been incorporated during the past year, treated 3,395 eye patients and 1,351 ear, nose and throat patients in 1922—a substantial increase over the figures for 1921. The financial statement showed a balance of £27 on the year's working; the amalgamation of the two institutions has been justified both in the interests of economy and of efficiency.

## Ireland.

#### REFORM OF POOR LAW SERVICES.

THE Local Government (Temporary Provisions), 1923, Bill was debated in the second reading stage at recent meetings of the Senate of the Free State. One speaker pointed out, with regard to the hospital arrangements provided under the schemes for the amalgamation of workhouses; that in some of the Limerick districts patients had to travel twenty-seven miles to the County Hospital, and, to make matters worse, had, in some instances, to wait two days before an ambulance was available to remove them to hospital.

Mr. E. Blythe (Minister for Local Government) said that the bill, although it did not bear it on its face, was an act of indemnity during the period of the struggle which went on in the country when great changes were effected in Poor Law administration without any definite legal sanction, and the bill was necessary for the purpose of regularizing what had been done and to prevent endless confusion and litigation. If it were not for that, it might be possible to carry on as at present, until permanent legislation for dealing with local government could be introduced. The preparation of permanent legislation had been begun, and he hoped within three or four months it would be possible to bring it before the Dail. He would not claim that all the schemes were perfect, but they had been steps in the right direction, and the economies effected had been very considerable. There had been counties in which the economies amounted to £40,000 a year. The restrictions mentioned in regard to the granting of outdoor relief had been removed of necessity after the closing of the workhouses, and no destitute person could be allowed to starve. It was desirable to rid county homes of the horrible character attached to the workhouse, and to make them places where honest people could go in their last days. They desired to set up in each county a good county hospital very much above the standard of the general run of the workhouse hospitals. A certain number of such hospitals would come a spurious demand for the opening of such institutions, and it would not be right to yield to such clamour.

#### FOOD INSPECTION.

At a combined general meeting of the Ulster Branch of the British Medical Association and the Ulster Medical Society, held on March 2nd in the Medical Institute, Belfast, Professor Johnstone, F.R.C.S., M.P., in the chair, the following resolution was passed and ordered to be sent to the Ministers of those departments of the Parliament of Northern Ireland which take cognizance of such matters:

That any Public Health Authority should have the right to examine and inspect the source of supply of any article of food offered for sale or consumed within its area.

## Correspondence.

#### REGISTRAR-GENERAL'S STATISTICAL REVIEW, 1921.

SIR,—The Registrar-General cannot be congratulated on the latest issue of his "Annual Report" under the guise of a "Statistical Review." The first criticism which has to be made is the change in size of the publication, which is now royal octavo instead of folio foolscap. There is, in consequence, in some of the tables, some crowding of small type which renders the reading of the figures an effort for those who are not blessed with normal vision, especially if artificial light be used.

In the next place the "Review" is to be completed in three parts, and as Part I is priced at 10s. it is reasonable to suppose that the cost of the three parts will be round about 30s. In 1913 the one-volume Report cost 5s. 9d. A letter from H.M. Treasury justifying the increased charges for official publications appeared in the January issue of the *Journal of the Royal Statistical Society*. The examples cited in support of the contention that the sale of those publications has not been affected by the increase in price are not very convincing, being limited to the Registrar-General's Weekly Summary—a publication which the public can scarcely be expected to buy, as it is regularly summarized in the press—and the Annual Statement of Trade. The public generally ought to be encouraged to purchase and study a publication such as the Annual Report of the Vital Statistics of the Country, but this is not likely to happen when prohibitive prices are charged. Such documents should not be sold on an ordinary commercial basis.

It is a serious defect that the "text" of the Review has not

been issued simultaneously with Part I—a fact which has not prevented a reference to the "text" being included in the head note to Table 14 (p. 62). Since the Report for 1919 there has been no "letter" from the Medical Superintendent of Statistics to the Registrar-General. As those "letters" dealt with statistics for the proper analysis of which medical knowledge is essential, it is desirable that the inclusion of such "letters" should be resumed. Such "letter" should certainly have been included in this part of the Review.

In his preface to the volume under consideration the Registrar-General observes, "an endeavour has been made to regroup the statistical matter according to the distinctive character of its interest. The tables have thus been divided into (1) medical statistics and (2) civil statistics." He goes on to say, "It seemed probable, particularly in view of the increased scale of prices for Government publications now prevailing, that sections of the public would find it of advantage to be able to obtain a part in which they are specially interested instead of being obliged to purchase the whole publication." It may, therefore, be concluded that the Registrar-General considers that statistics of natality are not medical or—to use a wider description—that they form no part of vital statistics. Medical statisticians are not likely to endorse such a conclusion. To them, especially if engaged in public health work, the study of "income" (natality) is of as much importance and interest as that of "expenditure" (morbidity and mortality), critical examination of the latter being of little profit without taking into account the former.

When the Local Government Board published the Return of Notifications the data for any year were issued within something like six months after the expiration of that year. Part I of the Review, published last month, contains the Notification Statistics for 1921, so that publication of those figures has been delayed some nine or ten months.

On comparing the tables now issued with those contained in the Report for 1920 some important omissions will be noted. It is perhaps desirable to defer comment on those omissions until the issue of Part II, as the missing tables may appear as "civil statistics," which they certainly are not. The table of "Causes of Death at Different Age Periods, 1921" (Table 17, pp. 124–208) is most inconveniently arranged with the causes of death at the top and the ages at the side. Moreover, the numerical sequence imposed by adherence to the International Schedule of Causes of Death is frequently interrupted, and causes with very small numbers are relegated to footnotes. The use of the table promises to be laborious, and the risk of mistakes in taking out figures considerable. Comparison of the tables on pp. 124–208 of the Review with the corresponding tabulation on pp. 140–241 of the Report for 1920 is greatly in favour of the latter.

When the foolscap series of Reports was initiated in 1912 the advantages attaching to the substitution of sanitary (administrative) for registration areas was emphasized. (See p. viii of the Report for 1911.) For the years 1911–20 (See p. viii of the Report for 1911.) For the years 1911–20 short tabulations of deaths by cause, sex, and age were given for every sanitary area in England and Wales. The Registrar-General has now excluded from the tabulation to be found on pp. 365–414 of the Review all urban and rural districts having populations of less than 10,000.

To determine the effect of the change the figures for Oxfordshire have been examined. Table 14 (p. 86) shows that that county includes eight urban and eleven rural sanitary districts, of which one urban and six rural districts appear in the table on p. 393. Of the 453 deaths occurring in the aggregated urban districts, 278 (61.3 per cent.) are excluded from Table 21, and of 1,124 deaths in rural districts, 413 (36.7 per cent.). Those who have tabulated the deaths for the smaller areas will be unable to continue the work and have to be content with a group "Rest of . . . Districts" to be obtained by subtracting the figures given in Table 21 from the totals for "Aggregate . . . Districts" to be found in Table 20 (p. 332). While the data for the smaller districts for individual years may be of slight significance, the study of those data over a series of years cannot fail to be instructive. If considerations of space have been the reason for the exclusion, it may be pointed out that there are possibilities of saving much space by eliminating the repetition which has been allowed in Tables 26 and 27 (Notification Statistics), where data for every sanitary area are to be found. Such saving of space can be effected, it is believed, without sacrificing a single district.

It is to be regretted that no tabulation of institutional deaths has been given. With the existing changed housing conditions the practice of removing the sick to nursing homes

or institutions has enormously increased. It appears to be very desirable that data for the examination of the extension of the practice year by year should be available not only as regards deaths, but also as to births, and, if possible, notified diseases.—I am, etc.,

London, W., March 10th.

REGINALD DEDFIELD.

#### DERMATITIS FROM DYED FUR.

SIR,—As a certain amount of public interest has been manifested lately in the subject of dermatitis due to dyed furs it may be appropriate to give a preliminary account of some observations I have been making on this matter in the skin department of St. Bartholomew's Hospital during the last three months.

In the first place it should be pointed out that many thousands of women are wearing "beaver coney" collars without any ill result, and that even the large number of patients with dermatitis due to this fur which have lately been seen in every dermatological clinic must form but a very small percentage of the total wearers. In the second place it may be emphasized that this is no new phenomenon, although it is more widespread just now than usual. Cases, for example, have been reported in 1913 by Blaschko (*Deut. med. Woch.*, 1913, No. 49), in 1916 in America by Olson (*Journ. Amer. Med. Assoc.*, March 18th, 1916), and in 1922 by Rasch (*Ugeskrift for Læger*, April 13th, 1922).

Since January 1st, 1922, we have seen in the skin department at St. Bartholomew's Hospital thirty-three cases of women and girls suffering from dermatitis due to wearing "beaver coney" collars. This fur is rabbit, dyed brown. The patients' ages have ranged from 15 to 50 years.

The eruption is so characteristic that in several cases I have been able to tell a patient before she has said a word that she has been wearing a beaver coney collar. This eruption was well described by Dr. Semon in his memorandum on the subject in the *BRITISH MEDICAL JOURNAL* of March 17th. It consists in the early stages of a blotchy erythema, going on in some cases to superficial vesication with weeping and crusting. The eruption affects the back and sides of the neck in nearly all cases, the chin and the lower part of the face in the majority, but in my experience in only about one-third of the cases does it affect the upper part of the face and cause the oedema of the eyelids. The long axis of the patches on the sides of the neck is, as a rule, roughly horizontal or parallel with the lower border of the jaw. There is much itching and burning.

An interesting point is the length of time for which the different patients have worn their furs before the appearance of the rash. This has varied in my cases from two to twenty weeks, the average for ten patients who wore their fur collars at week ends only being eight and a half weeks, while for six patients who wore the collars every day it was just under six weeks.

Two explanations have been advanced to account for this latent period. Olson (*loc. cit.*) considered that it was only when the fur got damp from rain or perspiration that the dye was absorbed by the skin and the patient developed the rash for the first time. A more likely explanation seems to me to be that the delay is due to the patient gradually developing a sensitiveness to the irritant in question. In this connexion the experiments of Cash (*BRITISH MEDICAL JOURNAL*, October 7th, 1911) on the irritant properties of East Indian satinwood are of interest. Cash's experiments on himself and others showed that some people gradually develop an extreme sensitiveness to the irritant principles of this wood as a result of repeated local applications, and that this sensitization involves the skin of the whole body and not only the area treated.

In this connexion again the experience of one of my patients is of interest. She had taken eleven weeks to develop the rash on her neck, but after, at my advice, removing the fur collar from her coat, she carried it over her arm for a few minutes, and within twenty-four hours developed on her wrist, where the fur had rested, the typical erythema. On the other hand, I have seen at least two patients with collars and cuffs apparently of the same fur who had the rash on their necks but not on their wrists.

The rash in the majority of cases begins to get better as soon as the fur is left off and suitable local treatment commenced, but in some patients who have had the eruption a long time the whole skin has seemed to develop a general hypersensitiveness, and such patients may take a long time to get well.

Many materials used in dyeing furs are amino-derivatives

of benzene, naphthalene, etc.; others are benzene derivatives containing amino- and oxy-groups. In most or all previously reported cases the dye incriminated has been paraphenylenediamine, often known in the trade as "ursol," which is also the active principle of a popular hair dye well known to produce severe dermatitis in sensitive persons. In the oxidation of paraphenylenediamine an exceedingly irritating substance, chinodichloridimine, is formed, and it is possible that in the cases under consideration this substance has been left in the furs owing to insufficient oxidation and to incomplete removal of surplus dye in the finishing process.

Through the kindness of Dr. T. M. Legge of the Home Office I got into communication with two prominent firms in the London fur trade. They both tell me that they have never had any complaints about furs dyed by themselves, and also informed me that much cheaper beaver comes from the Continent, especially from France and Belgium, and also from the U.S.A. I showed to these experts independently six specimens of furs worn by my patients. One said that all the six came from France and probably from the same dyer, or at all events were dyed with the same dye. The other would not commit himself further than that they had all been dyed on the Continent. The latter gentleman now has the six samples of fur in question for investigation, and he and I with Dr. Mackenzie Wallis hope to publish an account of our findings at some future date.

In the meantime I may add that the London Fur Trade Association and the Ministry of Health have had the matter under investigation for some weeks. I am much indebted to Dr. Adamson for giving me charge of these cases, and to Dr. T. M. Legge of the Home Office and Dr. Allan C. Parsons of the Ministry of Health for their assistance and information.—I am, etc.,

A. C. ROXBURGH, M.D. Cantab., M.R.C.P. Lond.,

March 17th.

Chief Assistant, Skin Department,  
St. Bartholomew's Hospital.

SIR,—I have read with interest Dr. Semon's note on the subject of dermatitis from dyed fur, as undoubtedly this trouble is very frequently met with in the out-patient departments at present. The diagnosis usually presents very little difficulty, as the erythema tends to appear in rectangular patches on either side of the neck, and on both wrists if fur cuffs are worn. The cause is undoubtedly the wearing of cheap furs—that is to say, rabbit skins which have been dyed in imitation of the more expensive skins. The furs seem to be innocuous unless the wearer has a greasy skin, when the colouring agent appears to dissolve in the fatty acids. The type of fur which seems to be chiefly to blame is that which is known in the trade as "beaver dyed coney." The chief dyes used are as follows:

Light brown	Pyrogallic acid.
Medium brown	Metatolylene diamine base.
Dark brown	Metatolylene diamine base.
Red-brown	Metatolylene diamine base.
Deep black	Metatolylene diamine base.
Blue-black	Nigrosine and nigrosine with paraphenylenediamine.

The cheap furs are apparently not finished—that is to say, the mordants used are not neutralized.

From the following description of the preliminary treatment of the furs it will be seen that some very powerful chemicals are employed, and it appears to be doubtful whether it is an unneutralized mordant or the dye itself which causes the dermatitis.

#### Dyeing Methods.

Before dyeing the hairs must be degreased. This process is carried out according to the hardness of the hair, with a solution of 1 to 2 per cent. of soda, or with soap lye containing 1 to 2 grams of ammonia per litre, or most thoroughly by the application of milk of lime (about 20 grams quicklime per litre) or by immersion in lime water. This process may be omitted, however, in the case of very soft, clean skins, or skins bleached with hydrogen peroxide.

Artificial dyes, or chiefly intermediate products (amines), are used in dyeing, either alone or together with natural dyestuffs.

In order to increase the affinity of the hair, it may be subjected to a preliminary treatment with bleaching powder, about 5 grams per litre for light and 10 to 15 grams per litre for dark shades. In the clear solution the skins are soaked for two or three hours, soured with hydrochloric acid (20 to 35 c.cm. per litre of water), and well rinsed. Particular care must be taken to see that the chlorine is completely removed, and if there is any doubt the rinsing should be followed by a treatment with a lukewarm solution of bisulphite (about 50 c.cm. per litre).

As mentioned, fur dyeing is done chiefly with amines, such as paraphenylenediamine and para-amido-phenol, aniline, etc. The organic amines, which are marketed as "ursols," "furols,"

"fantols," etc., are usually dyed on unmordanted skins for light shades and on mordanted skins for medium and dark shades. The most usual mordants are potassium bichromate and the sulphates of iron and copper, which are used in baths of weak acids, such as tartaric or acetic. With bichromate alone, red or brown shades are obtained; copper sulphate (or mixtures of that salt with bichromate) gives greener shades, which are still greener with ferrous sulphate. For black, mixtures of iron and copper salts are used. For dyeing with aniline black, the bath is prepared according to one or two methods. Sometimes it consists of a solution containing hydrochloride, or instead, aniline nitrate, sodium chlorate, ammonium chloride, copper sulphate, ammonium vanadate, and sodium bichromate, and sometimes aniline oil, nitric acid, sodium chlorate, copper sulphate, and ammonium vanadate, according to the method employed.

When using the amines on unmordanted furs, a larger quantity of the base is required, so that the solution must be much stronger. When the colour base has been dissolved in warm water, and diluted to the proper strength with cold water, after about an hour 12 volumes of hydrogen peroxide are added in quantities of 10 to 15 c.cm. per gram of the colour base for mordanted and of 30 to 35 c.cm. for unmordanted goods.—I am, etc.,

London, W., March 17th.

WALTER F. CASTLE, M.B. Cantab.

#### IONIC MEDICATION.

SIR,—Dr. David Campbell's article expressing the views of a pharmacologist on ionic medication will be welcomed by all electrotherapists, especially by those who for the past four years have been exposing the fallacy of the theory of ionic medication on identical grounds and by similar experiments to those upon which Dr. Campbell bases his reasoning.

It must not be assumed, however, as Dr. Campbell almost seems to imply, that because the theory of ionic medication is erroneous, therefore the actual benefits from prolonged, intensive, and repeated applications of the constant current are thereby in any degree lessened. The value of such treatment, when properly administered, is now far too well established to admit of any doubts as to its great curative power. When failure results, such failure will be found to be due to the method of application, or to its adoption in unsuitable cases. When we consider that the constant current, the so-called "ionic medication" or "ionization," is commonly ordered by medical men who have no knowledge of electricity or its mode of action, and that the treatment is generally carried out by those who have no knowledge of medicine or of the nature of the diseases they are treating, it is remarkable that benefit is so often obtained.

The necessity for the administration of electrical treatment either by or under the direct supervision of a qualified medical man possessing some knowledge of the therapeutic action of electricity is well shown in the treatment of such conditions as primary sciatica and brachial neuritis, conditions which yield far more readily to electrical treatment than to any other remedy. Where such treatment is applied without suitable supervision by attendants with no medical knowledge the common radical origin of this trouble is frequently overlooked, and the pads are placed on opposite sides of the limb at the points to which most of the pain is referred, with the result that the seat of the lesion is untreated, and, at the best, mere temporary relief of the pain, due to counter-irritation, can be hoped for. Or, again, cases of secondary sciatica, due it may be to sacro-iliac strain, sacralization of the lumbar vertebrae, to an untreated infective focus, or to pressure from a new growth, are submitted to a prolonged course of electrical treatment with no prospect of lasting improvement.

Dr. Campbell in his interesting paper appears to me to underestimate the beneficial effects obtained from the heat generated during prolonged, intensive, and repeated treatments by the constant current. The main arguments in favour of the heat so generated being the most important factor may be briefly summarized as follows:

1. The improvement obtained by this form of treatment is such as might be expected to result from a prolonged supply of heat energy to the part treated—namely, relaxation of spasm and consequently temporary relief of pain, an increased blood supply with consequent improved nutrition of the part, increased resisting power, and, if the treatment is continued for some weeks, some absorption of fibrous tissue and increased mobility of the joints in rheumatic and other cases.

2. According to Joule's law, it is calculated that as much as 2,000 calories can be generated by the treatment of a sciatic limb by the intensive constant current of 40 to 50 minutes' treatment:

3. The skin temperature, recorded by a surface thermometer, of a sciatic limb 2° F. below that of the normal limb before treatment can be raised by the constant current to 2° F. above that of the normal limb at the end of the treatment. The thermometer employed in the series of treatments upon which this statement is based was placed on the skin far removed from the pads conveying the current, and hence the rise of temperature could not have been directly affected by dilatation of the skin vessels arising from either the polar action or the electrolytic action of the salts with which the pads were moistened. Neither could the rise of temperature recorded have resulted from the direct heating of the skin at the point tested, for according to the law of branched circuits a very small amount of current would be carried by the high resisting skin at this point.

4. Therapeutic results, practically identical, are obtained from the diathermic (which admittedly produces its results by its heating action) and the constant current, provided that approximately a similar strength of current is employed in each case.

If not convincing, these facts are certainly very suggestive. —I am, etc.,

Oxford, March 14th.

W. J. TURRELL.

### LUNACY LAW AND THE TREATMENT OF THE INSANE.

SIR,—From the interesting article with this heading in your issue of March 10th I gather that there are those who promulgate the view that if and when more enlightened notions prevail among the community it will not matter where a "mental" case is treated, or what the institution is called, "so long as the most effective treatment is secured." This expression of opinion, taken with the concluding lines of the article, entitles us to assume that it is considered by some that provision for treatment of incipient insanity can be made as well in connexion with mental hospitals as elsewhere. As long as "the most effective treatment" is secured it will make, that is to say, no difference to me, being in the state of incipient insanity, whether I am sent to the erstwhile Munich Psychiatric Clinic (now Deutsche Forschungsanstalt für Psychiatrie in München), or to some "Irrenanstalt" in Bavaria; to the Maudsley Hospital, or to a county asylum in Surrey or Kent.

Now, I have, in a memorandum drawn up for the guidance of my family for use in the event of my being seized with incipient insanity, expressly warned my relations against the sophistry and the fallacy which are wrapped up in the above teaching. In any given district the "most effective treatment" is to be secured from that galaxy ("assemblage of splendid persons") which is constituted by the staff of the general hospital; if, haply, the latter is in connexion with a medical school, the constellation is still more splendid. The hospital connotes the medical complex. What do these high priests of medicine, with their attendant acolytes ("teams") and abetting alchemists, know or care about the "asylum," its "inmates," and the Peculiar People who minister to these? As well discourse to them of Ur of the Chaldees; of ushabtis, ju-jus, and gargoyles; of far-away sorcerers. Yet we require the whole of this galaxy—and no mere counterfeit of it—to get busy amongst the incipient mental cases, and to regard them as their cases. The "most effective treatment" is not to be "secured" by occasional visits of members of the hospital staff to mental hospitals. The leper must go to the sanctuary, and abide therein. The place where the early mental patient is to be treated must, I believe, be entirely divorced from the mental hospital, and be part of the general hospital system; supported and administered, very probably, by the local authority, but, nevertheless, definitely in the hospital orb. The staff of this place will, in return, give, for what it is worth, such special experience as they may possess; unfold such beliefs as they, by uncertain tenure, may hold.

Such a place would have a status in the eyes of the hospital staff; at such a place, but not in connexion with a mental hospital, will the "most effective treatment" be "secured."

Therefore, in the event of the contingency arising, my said memorandum requests that I be taken to this place (if such can be found); not to the mental hospital, nor even to its purlieus; for hope doth not flourish in the miasm of chronicity, nor recovery take its beginnings from soil encumbered with end-products. And my memorandum further declares that my mind is not set against the Psychiatrist, should the high priests of medicine desire to take counsel with him.

etc.,  
Cardiff City Mental Hospital,  
March 15th.

EDWIN GOODALL.

### TREATMENT OF EARLY MENTAL CASES.

SIR,—In your issue of February 24th I notice that in the course of an article on early mental treatment you mention that the head of Staffordshire County Mental Hospital calls attention to statistics which are stated by him to prove how very small is the number of slight mental cases who presented themselves for medical treatment while still in the "uncertifiable" stage. A great deal depends naturally upon the doctor's estimate of the degree of loss of balance which constitutes certifiability. A mental specialist, when called in, is inclined (possibly from his familiarity with certain modes of interrogation) to certify many a case about whose committal the family doctor, who knows the patient well, would hesitate. In fact, his hesitation is the usual cause of delay.

We must bear in mind the patient's extreme dread of an asylum and the disinclination on the part of the relatives to use force to effect a transfer to such an atmosphere. Since force or subterfuge is pretty sure to be resorted to in the end, the evil day is naturally postponed as long as possible, the patient being meanwhile subjected to accumulated discomfort, distrust, and acute apprehension—conditions which do not tend to reassurance and recovery.

It is impossible to arrive at a true estimate of the number of slight mental cases amenable to early treatment until some reasonable provision is made for such an environment as will not tend to accentuate the dread and depression of the troubled soul. This can only be done by providing homes or hostels run on a hospital footing—that is, free from detention and unconnected with lunacy—for the benefit of those not bad enough to be certified. This common-sense expedient for dealing with the beginnings of insanity by the supply of attractive sanatoriums would soon revolutionize all our theory and practice in regard to those transiently unbalanced. The Board of Control possesses no jurisdiction over the uncertifiable, and no legislation is needed to permit people to enter hostels where they run no risk of being detained. There is a strong body in Parliament, drawn from all parties, who have on several occasions presented a memorial to Health Ministers drawing attention to this most practical method for the cure of uncertifiable cases. Such homes could be started without any delay under the health committees of borough councils already empowered by the Public Health Act to run hospitals for any class of illness.

Instead of allowing common sense to be his guide each successive Health Minister is led by the lunacy authorities to frame a bill which, under the specious title of "Reform in Lunacy," is intended to diminish or annul the safeguards provided by the Lunacy Act, and to set up institutions under the Board of Control which shall serve as feeders to asylums. No wonder that early cases are averse to entering them. The Maudsley itself labours under the disadvantage of being numbered among the L.C.C. asylums, and consequently subject to lunacy administration and control.

Ministers will discover sooner or later that it is desirable to lend an ear to what public opinion has to say upon the urgent necessity of providing suitable sanatoriums for early cases as an alternative to asylums. Detention without certification—that is, without proper judicial inquiry—is both illegal and unjust. All patients who are dangerous and unfit to be at large ought to be certified, and no others. In a very large number of cases at present relegated to asylums there is no disease at all, only an exacerbation of the results wrought upon us all by the vicissitudes, the strains and shocks and stresses which we meet with in our journeying through life. The temporary loss of balance has been, in such cases, the result of adequate natural causes, and natural means must be resorted to for recovery. To place these patients under distressing conditions is the surest way to bring about the evil which we are endeavouring to avoid. They need fresh air and sunshine, occupation, interest, and cheerful surroundings.—I am, etc.,

S. E. WHITE, M.B., B.Sc.

London, E., March 12th.

P.S.—Lord Cave has just informed us that a "bill is about to be introduced to supply machinery for dealing with mental cases of doubtful character, before passing them on to the machinery allowed by the present law." Since no bill is needed to permit anyone to enter a hospital, and since the Lord Cave specifies that he refers to voluntary patients, the mention of some device for allowing them to be so dealt with, accompanied by another device to enable the patient, "if

mentally able to do so, to withdraw consent, and resume full liberty," indicates in a suspicious manner that there is more herein hidden than meets the eye.—S. E. W.

### HOSPITAL POLICY.

SIR,—Mr. Bishop Harman's vision of those who differ from him as myopic "sleek men who sleep o' nights" in "pleasant places" is amusing and no doubt good propaganda, but it does not help much. It may indeed be that his Committee has got the Council floundering about in unpleasant places, from which it is difficult to see the wood on account of the trees.

The Council has acted in the matter in an unscientific way. We have asked for facts and been given opinions. My own opinion is that no hospital staff has asked for a "medical staff fund," nor is the failure of the voluntary system apparent. Probably the vast majority of hospitals are in the position of my own hospital—namely, it is ruled by a voluntary board, served by a voluntary medical staff, supported by voluntary contributions, and has no contract with anyone to take in any patient unless the medical staff recommends admission. The hospitals which I know have no intention of departing from this position at the present time, because it is a clear understandable position which has much to be said for it.

If the Hospitals Committee is so anxious to adopt a progressive policy it should be in the direction, first, of getting as many medical men as possible interested in hospital work. Instead of this, the new proposal tends directly to create a material vested interest. A medical staff will become a close corporation which will have a direct interest in not welcoming an increase to its members, and it beats me altogether to see the British Medical Association, which represents all medical men, lending itself to such a policy.

If the whole of this cumbersome policy has been built up in order to help young men who wish to be consultants, and who now do a great deal of work for very little return, then surely that is a matter which concerns the teaching hospitals more especially, and should be dealt with in another way; but meanwhile we want more definite knowledge of facts, and until that is given us we should drop the whole matter.—I am, etc.,

Letchworth, March 14th.

NORMAN MACFADYEN.

SIR,—In most of the letters and discussions about the hospital policy of the Association it is sought, by the analysis and division of hospital patients into various classes, to find some arrangement by which the British Medical Association can unite the conflicting opinions into one harmonious policy. Transferring for a moment our attention from the patients to the doctors, it appears that they are divided into classes even more difficult to combine under one policy than the patients. Among the doctors forming the hospital staffs throughout the kingdom there will be found:

1. Some who, whatever the policy of the Association, will refuse to take any payment for their services to any hospital patient.
2. Some who will accept, and probably demand, payment from one or more classes of hospital patient—for example, State-aided patients or members of a contributory scheme.
3. Some who think that the staff should have a share of every payment made by any patient to the hospital.

Although it is probable that these three classes include the great majority of medical men, yet no one can say with any certainty how the numbers are distributed, and there is a great danger that at the next Annual Representative Meeting, by the persuasive eloquence of a few members who really have clear-cut opinions on this subject and the debating power to press them, the majority, whose opinions, so far from being clear-cut, are distinctly nebulous, may be induced to pass a resolution which at the best will be tacitly ignored by many hospital staffs, and at the worst might lead to a split in the Association.

The payment of hospital staffs is a complete departure from long-established custom; after two years of discussion we have not yet got a policy which meets with anything like general approval even among ourselves. Beyond this we have to consider, if and when we apply for a staff fund, what the probable attitude of the lay committees will be. Further than this, if we can convert the lay committees (which I very much doubt) we still have to consider the effect on the general public.

We also have to remember that this is a question which, although it affects the profession as a whole, yet is primarily

the concern of the staffs of the hospitals; it would seem an essential preliminary to any decision by the British Medical Association that there should be elicited from all over the country the opinion of these staffs. I would strongly urge that, either through the Divisions or by a direct inquiry from headquarters, the staff of every hospital in the kingdom should be invited to reply to the six questions set out in Dr. Fothergill's letter (BRITISH MEDICAL JOURNAL, December 30th, 1922, p. 1282, see also below). These questions put the matter in a much simpler form than any resolution I have yet seen. If we could have the answers to these questions we should at least know the opinions of the men most intimately concerned, and might be saved from the mistake of putting on record a policy which the staffs might reject. A further source of information which would be helpful is the number of hospitals which have already established staff funds. A resolution was passed at the last Annual Representative Meeting that this information should be obtained and given to the Divisions for their guidance. Has the Council yet got this information?

Possibly all this has been said before, but in a question of such cardinal importance it would be a disaster if the Association committed itself without being very sure of its ground. Unless there is clear evidence that the great majority of the profession are agreed, it would be far better to postpone any decision until such agreement is achieved.

The six questions of Dr. Fothergill's letter referred to above are:

Do you consider that contributions to a staff fund should be made from—

1. Gratuitous contributions, existing hospital assets, endowment funds, and the like.
2. Payments made to the hospital by private patients, provided that the staff is allowed to charge fee.
3. Small payments made by individual patients, which are not recoverable by the patient from a third party, and which are not more than the cost of accommodation and maintenance.
4. Similar payments (as 3 above) which are more than the cost of maintenance and accommodation.
5. Payments made to the hospital by the State, municipal authorities, employers of labour, approved societies, insurance companies, or any other body which has entered into a financial arrangement with the hospital.
6. A contributory scheme under which there is a stated or implied return required from the hospital on behalf of the members of the scheme.

—I am, etc.,

Brighton, March 18th.

A. C. GEMMELL.

SIR,—The Chairman of the Hospitals Committee plumes himself mightily on the alleged success of his policy. I predict that his complacency will receive a rude shock at Portsmouth. He quotes a sentence from Lord Onslow's report in support of his novel definition of a voluntary hospital. Surely it would have been franker to quote the actual definition of this Committee, which is as follows:

"An institution (other than an out-patient dispensary) managed by a responsible committee and wholly or mainly supported from voluntary sources," etc.

Now Mr. Harman has plainly confessed that if his scheme proceeds, which it certainly will not, lay boards must be paid.<sup>1</sup> Whether "voluntary management" in the eyes of Lord Onslow's Committee embraces this contingency I know not, but I am aware that a single chairman of a large hospital values his unrequited services to his institution at £1,000 a year. Will Mr. Harman at long last now state, without further wriggling or evasion, who will provide all this money under any system where hospitals are "wholly or mainly supported from voluntary sources," and what shred of "voluntary control" will survive in these institutions under his scheme? I would yet again inquire how many staffs have so far approached their lay boards with his policy, and with what success, and when he proposes to approach his own? Why, if "close co-operation between lay boards and staffs" is essential, this policy was sprung upon us at such short notice that it was physically impossible for any consultation to take place between them before decision was actually taken, and advertised for a great deal more than it was worth? Why a matter of such importance was so artfully buried in nine lines of the fifty-four pages of the report of the Council, and why its rejection by Scottish staffs was deliberately suppressed in that report and ignored at Newcastle? As for the rest of his long letter, there is not a word in it that in any way reflects upon the policy which

<sup>1</sup> BRITISH MEDICAL JOURNAL, April 8th, 1922, p. 532.

I advocate, and which is set forth in a resolution recently passed by the Brighton Division to be circulated to all the others. That your readers may, however, attach due weight to the arguments of an authority so eminent I reproduce for their benefit his former words:

"He thought he spoke for most of those present when he said that they believed in the voluntary system so completely that they would like, if they could, to have the old voluntary hospital, of the old days . . . they wanted the nearest approximation to it that could be secured . . . this fine spirit of independence was of the greatest advantage to their professional life."

After this panegyric it is somewhat disconcerting to those unfamiliar with the versatility of his genius to find him, that same afternoon, promoting vigorously a policy concerning the financing of which under any sort of voluntary system he deigns not the smallest intimation, and which has been condemned, by no less authority than the Cave Committee, as a direct menace to the whole voluntary principle.

Presently we find him, at Newcastle, scoffing at the efforts of the Brighton Division to salve some remnant of that honourable tradition so lately the object of his affectionate regard, and thereafter, in the *Times*,<sup>2</sup> parading his opinion of the "greater fairness" of the Continental system, while advertising to all the world that the hospital policy of the Association should assist a consultant in Harley Street to be "enshrined in suitable and substantial elegance," and to be conveyed in a "handsome chariot" upon his rounds. The engaging candour of this confession acquires much added charm when we recall the long list of purely altruistic purposes circulated to us, towards which it was suggested the staff fund might with advantage be dedicated by less exalted honorary officers. I must not dwell on the urbanity<sup>3</sup> of his first remarks about myself when I had the hardihood to differ from him, and to express what proved to be the opinion of the majority of the profession and practically all lay boards, but would pass on to that dramatic moment, when, finding any reasoned reply inconvenient,<sup>4</sup> he waved me aside with fine disdain and threw himself upon the good offices of those "reasonable men," the lay committees of the West London Hospital, whom to this day he dare not thus approach, well knowing he would not be supported even by his own colleagues if he did. I would not, however, withhold due meed of praise to the originality he exhibited when, having scanned the whole horizon and dredged the very depths of his intellect for an outstanding example of the voluntary spirit free, unfettered, and uncontrolled, he selected<sup>5</sup> with amazing diagnostic precision—the British soldier under strict military discipline in time of war! Mr. Harman would explain the patent defeat of his policy at Glasgow by the alleged intervention of "comfortable places." Seeing that 150 amendments had appeared on the agenda sheet in 1922 where there were none in 1921, it is surely transparently clear that the sole reason for its temporary former success was that, owing entirely to the methods employed in its introduction, scarcely anyone had taken it seriously, or indeed considered it at all. Will he now explain exactly in what way Belfast, Bristol, Cardiff, Liverpool, Southwark, and Smithfield are more "comfortable" than Leicester?—I am, etc.,

Chichester, March 10th.

G. C. GARRATT.

Sir,—In communications appearing in your *JOURNAL* on pages 353 and 398 I suggested that the greatest confusion was rapidly arising with regard to the relative positions of hospitals, contributory schemes, and the medical profession, and certain principles were submitted for general approval, the adoption of which it was hoped would clear the issue.

Dr. Garratt in your last issue quotes one of these principles<sup>1</sup> but disregards others on which it depends<sup>2</sup>; he says that he is amazed, asks where the money is to come from, and adds that if such a "notion" were "propagated" it would militate

greatly against successful appeals for funds made by hospitals.

In order to determine the correctness of a principle it is not necessary to delay its adoption until some procedure has been elaborated under which that principle can be put into operation. The question is, Is the principle sound?

"Where is the money to come from?" The charitable public will find the funds required for the rapidly decreasing group, the indigent poor (15 per cent. of patients). The State, private patients, and all bodies contracting for additional medical services should be required to pay in full. Then there are left those suitable for insurance under a contributory scheme (2d., 3d., or up to 6d. per family per week) who should be able to pay for accommodation, maintenance, and medical services, whatever may be their individual financial position. These last two groups make up the 85 per cent. of patients. Until the general economic conditions are easier the charitable public probably will be willing to assist the last group and the doctors will do so by accepting only a percentage as recognition of the principle that this is a business undertaking and not a charity. (It is interesting to read that this last group, although paying nothing for accommodation nor for medical services, but only paying the maintenance, is loudly proclaiming that they pay for everything which they receive; that they have a right to it, and that there is no charity attached thereto. Some hospitals openly support this contention.) Does Dr. Garratt contend that this weekly payment is beyond the means of those who should be insured? If it is found to be so in some cases no doubt the charitable would assist to pay those premiums.

"If such a notion were 'propagated' it would militate greatly against successful appeals for funds." Does Dr. Garratt contend that appeals are a necessary part of a voluntary hospital? Cannot we visualize and work toward the day when whist drives, banquets, dances, concerts, bazaars, students' buffoonery, and all similar appeals will have been replaced by contracts drawn up on business lines with the State, private bodies, and groups of individuals to pay not only in full for additional medical services, but also a small amount over; which margin, together with regular charitable subscriptions, will put at the disposal of boards of management ample funds with which to provide for the rapidly dwindling group of indigent poor the best of treatment; that day when, in fact, the recently imposed garb of self-advertisement and self-pleasing will have been removed finally from Charity? What a relief such a state of affairs would be to all!

In the meanwhile if hospital boards adopted the suggested principles and when appealing for funds stated specifically for which of the three groups the money is required, promising to use the money only for that group, the public would be in a better position to appreciate the situation. Whereas appeals now made are thought to be for the indigent poor the money received is really used to wipe out so far as it will go the debt caused through having entered into contracts to provide additional medical services at less than cost price for those well able to pay in full. The failure of an appeal which seemingly so distresses Dr. Garratt would really act as a wholesome tonic, because it would compel hospital boards to put their houses in order.—I am, etc.,

Hove, March 10th.

E. ROWLAND FOTHERGILL.

#### TREATMENT OF OPHTHALMIA NEONATORUM IN LONDON.

Sir,—In the *BRITISH MEDICAL JOURNAL* of March 3rd, p. 390, I see some criticisms of the existing arrangement for the treatment of ophthalmia neonatorum at St. Margaret's Hospital, also contrasting it with Liverpool. I would like to point out that in Liverpool the ophthalmia neonatorum department is attached not to the general hospitals but to St. Paul's Eye Hospital.

One, quite admits that a hospital devoted entirely to ophthalmia neonatorum is liable to be associated with venereal disease, although at St. Margaret's every precaution is taken against it and we have not had much trouble therefore, but I think this might still further be overcome by attaching an infants' welfare centre to it.

In your article you say that the Departmental Committee on Blindness think it would be advantageous that hospital accommodation should be provided by securing beds in teaching hospitals in centres convenient to the great masses of the population. It does not matter materially to the patients where the hospital is situated since the Metropolitan Asylum

<sup>2</sup> *BRITISH MEDICAL JOURNAL*, SUPPLEMENT, January 1st, 1921, p. 1.

<sup>3</sup> April 30th, 1922.

<sup>4</sup> *BRITISH MEDICAL JOURNAL*, December 24th, 1921, p. 1095.

<sup>5</sup> *BRITISH MEDICAL JOURNAL*, April 2nd, 1922, p. 552.

<sup>6</sup> *BRITISH MEDICAL JOURNAL*, April 8th, 1922, loc. cit.

<sup>7</sup> The tariff of payments fixed for this 85 per cent. should be such as to pay in full the whole cost to the hospital, including remuneration of the staff.

<sup>8</sup> Owing to the economic conditions at present existing the staff should be willing, temporarily, without prejudice and as a concession, to receive a nominal recognition of the services rendered, by means of a percentage payment. By this concession the Board of Management will be able to fix a lower tariff of fees than it otherwise could for the reception of this 85 per cent. Members of a contributory scheme, whatever their individual financial position may be, are no longer objects for hospital charity.

Board send ambulances to bring both the mother and baby to the hospital.

It is of the utmost importance for the sake of the children's health and also for the successful treatment of the disease in infants who are not accompanied by the mothers that they should be placed in open-air wards specially built for the purpose, which could not well be provided at any general hospital without building; also isolation wards have to be provided, both for the sake of the child and the mother.

With regard to the teaching of students, it seems to me that there ought to be no more difficulty in their attending St. Margaret's Hospital, which they do not do at present, than any of the fever hospitals as they do during the course of their training.—I am, etc.,

London, W., March 7th.

M. S. MAYOU.

#### GENERAL OEDEMA OF THE FOETUS.

SIR,—May I be permitted to call attention to the report (BRITISH MEDICAL JOURNAL, March 17th, p. 470) of some remarks made by me at a meeting of the North of England Obstetrical and Gynaecological Society, and to point out that they give expression to an opinion with which I do not agree? The histological appearance of the liver in general oedema of the foetus is certainly suggestive of leukaemia, and some of the earlier writers believed the condition to be of this nature. More recent observers, however, have shown that the small round cells seen in great numbers in the liver and elsewhere are not white blood cells, but are nucleated erythrocytes. The condition is not, therefore, a leukaemia, though at first glance this mistake might easily be made.—I am, etc.,

Liverpool, March 18th.

NORMAN B. CAPON.

#### THE RIGHTS OF A REGISTERED MEDICAL PRACTITIONER.

SIR,—The retired practitioner has been discriminated against before. In a lunacy certificate there is this clause: "I am a person registered under the Medical Act, 1858, and I am in the actual practice of the medical profession." I have always regarded this as an infringement of the privileges of the profession.—I am, etc.,

Rotherham, March 18th.

GILBERT E. MOULD.

SIR,—Is the distinction between a practitioner in actual practice and one not in actual practice quite an innovation? It is found in the "Certificate of Medical Practitioner," Lunacy Act, 1890, Second Schedule, Form 8. I am not sure that anyone knows what it really means. It should certainly not be put into any more Acts or Regulations.—I am, etc.,

Birmingham, March 20th.

WALTER R. JORDAN.

### Universities and Colleges.

#### UNIVERSITY OF LONDON.

NOTICE is given that among members of the Senate vacating office next May is Dr. T. D. Lister, elected by the graduates of medicine. Nominations should be sent to the Clerk of Convocation, at the University, not later than April 4th. Dr. Lister is eligible for re-election.

#### NATIONAL UNIVERSITY OF IRELAND.

OWING to the death of the Registrar, Sir Joseph McGrath, LL.D., the meeting of the Senate on March 16th was adjourned to March 27th, and a resolution of regret and sympathy was passed unanimously and ordered to be transmitted to the family.

#### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

##### Council Election.

THE following Fellows are candidates for election to the Council: Sir Herbert Furnivall Waterhouse (F. 1890); James Berry (F. 1885); John Herbert Fisher (F. 1893); Herbert John Paterson, C.B.E. (F. 1897); William Sampson Handley (F. 1897); Thomas Percy Legg, C.M.G. (F. 1897); Victor Bonner (F. 1899); Donald Armour, C.M.G. (F. 1900); Percy Sargent, C.M.G., D.S.O. (F. 1900); George Ernest Gask, C.M.G., D.S.O. (F. 1901); George Grey Turner (F. 1903).

The death of Sir William Thorburn increases the vacancies from four to five.

Voting papers will be issued on April 3rd.

#### ROYAL COLLEGE OF SURGEONS IN IRELAND.

THE following have been appointed to professorships in the schools of surgery: Medicine, P. C. Purser, M.D., F.R.C.P.I.; Midwifery, E. Hastings Tweedy, F.R.C.P.I.; Preventive Medicine and Medical Jurisprudence, V. M. Synge, M.D., F.R.C.P.I.

### Obituary.

#### SIR WILLIAM THORBURN, K.B.E., F.R.C.S.,

Consulting Surgeon, Manchester Royal Infirmary.

THE announcement of the death of Sir William Thorburn on Sunday last, March 18th, will cause great regret among a wide circle of friends and old pupils. He had removed from Manchester to London only a few months ago, shortly after the death of his wife, and then appeared to be in his usual health. Although he felt severely the loss of his two sons in the war, he returned from his service with the British Mediterranean Force in apparently good health and with renewed energy. He had been ill for about two months, and his death was not unexpected by those who were closely associated with him.

William Thorburn, who was born on April 7th, 1851, was the son of Dr. John Thorburn, professor of obstetric medicine at Owens College, where William Thorburn received his medical education. He was a brilliant student. He graduated in the University of London B.Sc. in 1880, M.B., B.S. in 1884, with gold medals in medicine and obstetrical medicine and surgery, and M.D. in 1885 and the F.R.C.S. in 1886. He became house-surgeon at the Manchester Royal Infirmary in 1883, and after filling other offices was elected honorary assistant surgeon in 1889, and succeeded the late Walter Whitehead as honorary surgeon in 1900. He retired in 1921, becoming honorary consulting surgeon before his full period of service had expired, so as to be free to attend to his other duties and to allow promotion of his junior colleagues. At an early stage of his career in Manchester he came under the influence of James Ross, then working out his neurological researches at the Manchester Royal Infirmary. Thorburn directed his mind to nerve surgery and was awarded in 1890 the Jacksonian prize of the Royal College of Surgeons for his essay on the Nature and Treatment of Injuries to the Spinal Column and the consequences arising therefrom. As Hunterian professor at the College he delivered a course of lectures on the surgery of the spinal cord, which was expanded into a book published in 1889. He wrote many other papers on spinal cord and brain surgery, and he also contributed to the knowledge of the pathological results cervical rib may produce.

In the Bradshaw lecture delivered last December on the surgery of the nervous system he reviewed his experience of many years. His tone of disappointment on his results was not surprising to those who heard his conclusions on the subject of the operative treatment of traumatic epilepsy delivered at the Manchester Medical Society several years ago. Nerve and brain surgery was by no means his only interest, and he had a large practice in general operative work in Manchester. His great knowledge, fine memory, wide experience, and his powers of lucid, concise expression and ordered arrangement of material made him a great teacher; and his ward classes and clinical lectures were eagerly attended by students. His lectures and addresses were all very carefully prepared beforehand and more or less memorized.

Thorburn had, indeed, a clear thinking type of brain. At one time he took a great interest in the war game, or Kriegspiel, which was played in Volunteer circles, and he became skilful at it. He also had a good whist and bridge mind. His knowledge was pigeon-holed and card-indexed. As a speaker he was precise and had his argument arranged in logical and connected order and with no padding. In this way he conveyed the impression that he was a thorough master of the subject he was speaking on, and suggested to some the thought that he would have risen to as high an eminence at the Bar as he did in surgery had he chosen the former profession, and that his judgements would have been models of lucidity and commendable brevity. He possessed a great faculty of summing up the points of a difficult subject, and could crystallize the ideas expressed in a debate in a few well chosen and clear words. He was one of the Pellhams of life, preferring to stop before his audience had had enough of his discourse rather than to outstay his welcome. He would have made an ideal representative of the medical profession in Parliament. He was eminently fitted to command the applause of listening senates.

For many years before the war Thorburn was a much trusted adviser in the Council, the Senate, and the Faculty of Medicine of the University of Manchester, and his opinion on educational matters was highly appreciated by

his colleagues there and by those on the honorary staff of the infirmary. He took a broad-minded, sagacious, and long view of problems, picking out essentials and leaving the smaller matters to take care of themselves. His business and administrative capacities and his knowledge of detail were of much service on the subcommittee of the Board of the Manchester Royal Infirmary in planning the building of the present large and fine hospital on the pavilion plan. In later years his many calls to London interfered with his regular attention to university matters, to the great regret, not only of his fellow-workers, but also of himself, for he was always proud of his school and anxious that its students should succeed in examinations and in after-life.

During his year of office as President of the Manchester Medical Society he used his administrative and persuasive mind in helping to work out a closer agreement than already existed between the University medical library and the library of the Manchester Medical Society. This arrangement enabled the Medical Society to offer to its members a wealth of medical books and periodicals approached by no other society in the kingdom with a subscription of one guinea. The gain to the research workers of the university was also immense.

Sir William Thorburn was a member of the British Medical Association, and vice-president of the Section of Surgery at the Annual Meeting in Manchester in 1902. At the Annual Meeting in Cambridge in 1920 he opened the discussion on the end-results of injuries to the peripheral nerves treated by operation.

In recent years he took great interest in the work of the Royal College of Surgeons, both from the administrative and examining points of view, and he spent a great deal of time in London. He was on the Council for many years, and an examiner for the final examinations of the Conjoint Board and for the Fellowship of the College. He was a good and fair examiner for the average man, but did not suffer fools gladly. In recent years he examined in surgery for Oxford University. His work on spinal and nervous surgery and his great experience made him much sought after by railway companies or litigants in compensation cases, and he made an ideal scientific witness.

When the war broke out he was on the staff of the Second Western General Hospital in charge of the surgical section. Before long he went abroad as consulting surgeon to the British armies in the Mediterranean and saw service in Malta, Gallipoli, and Salonica, and he served also in France. He was a great source of strength to the officers of the R.A.M.C. in the districts where he worked. He received the C.B. (1916) and the C.M.G. and the Military K.B.E. (1919) for these services, and the honorary degree of M.D. from the University of Malta. Going away to the war in rather poor health, he came back, as he said, a new man and threw himself with renewed vigour into his professional work, especially that connected with the Royal College of Surgeons. He led a very active and busy life, and though his later years were saddened by domestic griefs he must have felt that he had fought a good fight and accomplished much. He was president of the St. Andrews Society of Manchester at the time of his death, and was deputy lieutenant for the county of Lancaster. He married Miss Melland, who, as has been said, died last year. He is survived by three daughters.

We are indebted to Mr. JOHN HOWSON RAY, assistant surgeon to the Royal Infirmary, Manchester, for the following:

In the death of Sir William Thorburn Manchester loses one of its most distinguished surgeons, and a man who had played a most important part in the development of its medical school, to which he was so devoted. As one of the pioneers in neurological surgery he will perhaps be chiefly regarded in the future, and there is no doubt that his painstaking investigations into the distribution of the peripheral spinal nerves (to which effort he was inspired largely by the late Dr. James Ross) at an early stage in his career led him to follow with undiminished interest the surgery of the central nervous system; and his last public address, the Bradshaw lecture, was on the surgery of the spinal cord. In neurological surgery Thorburn was thoroughly at home, and he displayed decided operative dexterity and resource in his laminectomies, in which he had a large measure of success. It was an inspiring sight to be present at one of Thorburn's operations on the spinal cord, where he carried out the various stages with precision, sureness, and artistic finish. In the Manchester Royal Infirmary he held many appointments in his time, and from the period when he was in charge of out-patients to that

in which he had control of wards his teaching was invariably of the best, and proved of the utmost value to many generations of students. As a lecturer he was unusually clear, concise, logical, and convincing. Of good address, dignified, and courtly to a degree, and with an excellent delivery, he could hold his audience with ease, and he never failed to be interesting whatever subject came under his review. He was animated by high ideals and did much to promote the cause of education in the Medical School of Manchester, taking his full share in drawing up the modifications in the curriculum necessitated by the development of medicine.

He was an excellent organizer, an ideal chairman of committee, and he rendered an enormous service in planning the details of the new Manchester Royal Infirmary in co-operation with the late Mr. Charles Hopkinson. As chief of a surgical unit he inspired house-surgeons, surgical dressers, and nursing staff to aim at the highest standard of efficiency and encouraged originality and research. Of a rather shy and reserved nature, he did not appear to make friends readily, but once his friendship was given it was lasting and loyal, and he was a highly valued colleague in the Royal Infirmary.

In the University he had been lecturer in operative surgery and in surgical pathology, and finally occupied the chair in clinical surgery, and in each position he was entirely successful. He had very wide interests, and his advice was sought in many fields in addition to that of surgery. For many years he had been a member of the Council of the Royal College of Surgeons of England, and an examiner in surgery at the College and in various universities. As an examiner he was fair-minded and reasonable, and displayed a quiet patience towards the candidate. At the outbreak of the war Thorburn was officer in charge of the Surgical Division at the 2nd Western General Hospital, but in 1915 he was appointed consulting surgeon to the Expeditionary Forces in the Mediterranean; at a later date he proceeded as a consulting surgeon to the Rouen area, and he has placed on record some of his experiences of overseas war work. On his retirement from the active staff of the Manchester Royal Infirmary in 1920 his colleagues on the Medical Board invited him to give annually a series of lectures on the surgery of the nervous system, thus marking their sense of his great service to the school, and their wish to retain the association with a colleague who had given so many years of a very active life to the work of the hospital.

JOHN IRVING, M.B., C.M. GLASG.,  
Consulting Surgeon, Huddersfield Royal Infirmary.

We regret to record the death, in the early morning of March 9th, after a week's illness, of Dr. John Irving of Huddersfield, who practised for nearly half a century in that town.

John Irving was born in 1850 at Sanguhar, Dumfriesshire, and studied medicine at the University of Glasgow. He graduated M.B., C.M. in 1873, and in the same year began his association with Huddersfield by becoming house-surgeon to the Royal Infirmary. In 1884 he was appointed honorary surgeon, and in 1905 consulting surgeon. His professional standing in the district is shown by the honours conferred upon him by his colleagues. He was twice president of the Huddersfield Medical Society and once president of the Leeds Medical Society. He had been chairman of the Huddersfield Division of the British Medical Association and a member of the local Insurance Committee from the time of its formation. Dr. Irving also took a large share in the public life of the district. He was made a justice of the peace for the borough in 1906, and carried out his duties as a magistrate to the admiration of all. On March 10th warm tributes to this work were paid by the chairman of the Bench and by the president of the Huddersfield Law Society on behalf of the solicitors practising at the borough police court. As surgeon to the local hospital, as magistrate, church officer, and member of the local St. Andrew's Society, Dr. Irving was a notable figure, respected and liked by all.

We are indebted to Sir JAMES BARR for the following appreciation:

By the death of Dr. John Irving I feel that there has been severed an unbroken friendship of half a century, which it is difficult to heal or replace, and this, I think, will be the feeling of all his old and young friends. Our friendship as students became more and more enhanced as we grew older in the battle of life. Irving, no doubt, grew in knowledge and

experience as time rolled on, but in wisdom he had very little to learn, as even when a student he was looked upon as a man of mature judgement who did not indulge in any of the frivolities of youth. Soon after graduation he gravitated to England as house-surgeon to the Huddersfield Infirmary, and from that town he rarely strayed except to indulge in his favourite pastime of curling. For many years there have been no opportunities for this game in England, hence he had to take those holidays in Edinburgh and Switzerland.

Dr. Irving became honorary surgeon to the Huddersfield Infirmary, where he rendered faithful and valuable services for many years, eventually becoming consulting surgeon. He was an enthusiastic admirer of the Leeds school of surgery, and had always unstinted praise for the brilliant achievements of Sir Berkeley Moynihan. He kept well abreast of modern developments in that ever-advancing branch of medicine. Although he laid no claims to brilliancy as an operator, and knew his own limitations better than anyone else, he was always considered a safe surgeon in whose hands a patient could repose with confidence; I know that his opinion was readily sought by his colleagues, and consultants were always ready to accept and act on his judgement. He did excellent work during the war, both to soldiers and civilians. His brethren who were at the front well knew that so far as Irving was concerned their interests were not neglected. He wisely eschewed medical politics as not suited to his placid temperament, but he took a warm interest in the work of the British Medical Association, and at one time was Vice-President of the Yorkshire Branch.

He was of the Puritan type, a man of great fervour and strong religious feelings, but he never tried to thrust his views down the throats of others. He was ever ready to try to raise the fallen and succour those in distress, a good Samaritan rather than a Pharisee: a Nathanael indeed in whom there was no guile. Although a strict teetotaler, no one could complain of his hospitality. I have sat by his side at a St. Andrew's dinner from 6.30 till nearly 2 o'clock the next morning, when John Barleycorn was, perhaps, more plentiful than the water, but he enjoyed the fun as well as the most hilarious of us. He always enjoyed a good Scottish joke, although he rarely perpetrated one.

For some years he had been liable to attacks of bronchitis in the winter, but with the last attack he was, I understand, only ailing ten days, and the end came rather suddenly and unexpectedly. He passed away peacefully in his sleep, dying as he lived, at peace with God and man. He has left a son and two daughters to mourn their loss. At the funeral there were a great number of his professional brethren, and it seemed as if the town of Huddersfield had turned out to do honour and reverence to the memory of a worthy citizen.

Dr. HERBERT NISBET ECCLES died on March 11th, aged 39. He was the son of Dr. G. H. Eccles of Plymouth, and received his medical education at Guy's Hospital. After taking the diploma of L.M.S.S.A. in 1916 he joined the R.A.M.C. on August 3rd of the same year as temporary lieutenant, and was promoted to captain after a year's service. He went to India, where he became x-ray specialist to the Bombay Brigade. He was invalided out of the service after three years, when he started practice at Plymouth, following his father and grandfather. His health, however, could not stand the strain, and he passed away at the house of his brother, Dr. G. T. Eccles of Hove. He was a member of the Plymouth Division of the British Medical Association.

Dr. ROBERT YOUNGER of Willington Quay, Newcastle-upon-Tyne, died after a short illness on March 11th. He was the youngest son of the late Mr. James Younger of Alloa and took the degrees of M.B., B.S. Durh. in 1902, and served as senior anaesthetist to the Royal Victoria Infirmary, Newcastle-upon-Tyne. He succeeded to the practice of his brother-in-law, the late Dr. Woodhouse, thirteen years ago. He was medical officer to the Post Office and surgeon to the Wallsend Slipway and Engineering Company. During the war Dr. Younger served with the R.A.M.C. and was wounded. He was a member of the Tyne-side Division of the British Medical Association.

The death occurred on February 26th of Lieutenant E. W. McQUAID, surgeon probationer in the Irish National Army, who was mortally wounded four days previously by Republican irregulars at Newport, co. Mayo. He was shot while attending a wounded National soldier, and, although seriously

wounded, gallantly carried his patient to a place of safety. Lieutenant McQuaid, who was 22 years of age, was the son of Dr. E. W. McQuaid, of Cooteshill, co. Cavan. He was a medical student of the Royal College of Surgeons in Ireland, and had recently been appointed demonstrator of anatomy and pathology.

## Medical News.

At a final meeting of the Oxford Osler Memorial Fund last week the honorary secretary, Professor J. A. Gunn, reported that the amount so far received was nearly £2,000. It was decided to place a bronze plaque in the University Museum; to found a memorial medal, to be awarded every five years to a graduate of the University of Oxford who has made some distinguished contribution to medical science; and to form an Osler travelling fund to assist teachers of the medical faculty to travel in the interests of medical knowledge and research. For this purpose alone a capital sum of £1,700 is required, and further subscriptions, which should be sent to Mr. A. P. Dodds-Parker, 2, Holywell, Oxford, are invited.

PROFESSOR A. V. HILL, Sc.D., F.R.S., of Manchester, has been appointed Jodrell Professor of Physiology at University College, London, in succession to Dr. E. H. Starling, F.R.S., who has become Foulerton Professor of the Royal Society foundation.

The house and library of the Royal Society of Medicine will be closed from Thursday, March 29th, to Tuesday, April 3rd, both days inclusive. The Wellcome Historical Medical Museum will be closed for cleaning and decoration from April 1st to 30th, inclusive.

A NEUROLOGICAL section is being established in the outpatient department of the Royal Northern Hospital, Hollo-way. It will be open every Friday at 1 p.m., on and after April 20th.

THE newly formed section of the Royal Microscopical Society which deals with industrial applications of the microscope will hold a meeting on Wednesday next, March 28th, at 7 p.m., when a number of instruments will be demonstrated and papers read.

THE annual meeting of the Society for the Study of Inebriety will be held in the rooms of the Medical Society of London, 11, Chandos Street, Cavendish Square, W., on Tuesday, April 10th, at 4 p.m. Dr. W. M. Feldman will open a discussion on racial aspects of alcoholism.

IN memory of the late Dr. W. H. Hender Bennett, for many years a member of the honorary medical staff of the Batley and District Hospital, it is proposed to endow a cot in the hospital and to erect a memorial stone over his grave.

M. SOVREL, senior surgeon of the Berck Maritime Hospital, will give a series of six lectures on the treatment of osteo-articular and glandular tuberculosis from March 26th to 31st. Each lecture will be followed by operations, fitting of plaster apparatus, etc. Further information can be obtained from M. Paris, Hôpital Maritime de Berck-Plage, Pas-de-Calais.

IN the Fifth International Congress of Historical Studies to be held at Brussels from April 8th to 13th, the history of medicine will be represented in the ninth section, which is devoted to the history of civilization. The subscription of 50 Belgian francs is payable to the treasurer, Professor C. Terlinder, 61, Avenue Legrand, Brussels. Further information can be obtained from the General Secretary, Ve Congrès des Sciences Historiques, Palais des Académies, Rue Ducale 1, Brussels.

THE Confédération des Travailleurs Intellectuels Français, which is merciful enough to use the contraction C.T.I., is summoning an international congress of C.T.I. to meet in Paris on April 5th. It will assemble under the presidency of M. Léon Bourgeois, senior French delegate to the Society of Nations. Other representatives of that Society, of the International Labour Office, and of several nations, will be present. It is hoped at this congress to form a Confédération Internationale des Travailleurs Intellectuels (C.I.T.I.). Further information may be obtained from the Secretary-General of the French C.T.I., 12, Rue Jenner, Paris.

AN International Tuberculosis Congress will be held in Madrid next month under the patronage of King Alfonso.

Dr. GIUSEPPE CARONIA has been nominated professor of clinical pediatrics in the University of Rome in succession to the late Professor Luigi Concetti.

AN appeal has been entered by the plaintiff against the judgement given against her by the Lord Chief Justice, on the findings of a special jury, in the libel action: *Types v. Sutherland* and another, reported in the BRITISH MEDICAL JOURNAL of March 10th (pp. 445-445).

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 1630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Iractis*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

"S." asks for information as to untoward immediate and remote general or nervous symptoms that have been observed, directly or indirectly attributable to the administration of vaccines in large doses or over a lengthy period. He would also like references to the subject.

#### LUNG DISEASE AND WIND INSTRUMENTS.

"EMPHYSEMA" writes: I should be very grateful to have some advice in the following matter. A man aged 39 developed catarrhal tuberculosis (without consolidation) in 1912-13. He had a mild attack of haemoptysis, passed one winter season in Switzerland, and has been free from active symptoms since 1914. The lesions were localized to the apex of the right lung and the middle lobe, and appear now to be in a fibrous condition. The patient would like to know whether any bad—or possibly good—effects would come to him from an habitual performance on one of the wooden reed instruments—the clarinet, the oboe, or the bassoon. The first instrument appears to me the most appropriate one; the oboe necessitates frequent holding of the breath, and the bassoon requires more power. Is it possible for any of the above mentioned instruments to produce emphysema, and would this be harmful to my patient?

#### INCOME TAX.

"SURGEON LIEUTENANT R.N.," who purchased a car in December, 1922, to use partly for pleasure and partly for attending classes some distance from his station, asks whether anything is allowable for this expense or for the fee charged at the classes.

\* If it is a specific condition of our correspondent's appointment that he shall attend these classes we consider that he is entitled to the minimum necessary expense—that is, in this case the train fares and the class fee; otherwise he is not entitled to any allowance for the expense incurred in improving his professional knowledge. Any allowance due should be claimed from the Assessor for the Admiralty, who is responsible for the correct assessment of his naval pay.

#### Car Transactions.

"C. F." bought (1) a 9-h.p. in 1908 for £215 and sold it in 1911 for £15; he then bought (2) a 15-h.p. for £315 and sold it in March, 1923, for £50, buying a 10/23 h.p. (R.A.C. rating=9 h.p.) car for £375. The expense of replacing (1) may have been dealt with in 1911, but is in any case now out of date. The expense of replacing (2) is £375-£50=£325, and that sum is an allowable professional expense as at March, 1923—that is, of the year 1923 if "C. F." bases his return on the three calendar years ending December 31st, or of the year 1922-23 if he takes the three years to March 31st; in the former case his income-tax liability is not affected until the financial year 1924-25.

"W. F. B. S." bought a four-seater in 1921 and sold it for £190 in 1922, buying a two-seater for £235. The expense of replacement is £235-£190=£45, and no more can be claimed. But our correspondent should note the facts for future use, as a further allowance will be due if he replaces his present car by a superior one at a later date.

"SCODEN" sends two sets of car transactions. In the first the allowance to be claimed is £495-£203=£292—that is, the actual cost of replacement, seeing that the cost of this new car is no greater than that of the original car when purchased. In the second case, as an improvement has been effected through the replacement, the amount to be claimed is £250-£30—that is, £170, and not £395-£30=£365.

"W. G. S." sold a 10-h.p. Swift (cost when new £210) for £70 and bought another make for £470. The profit on the sale was £140.

### LETTERS, NOTES, ETC.

#### RAT-BITE FEVER.

CAPTAIN S. K. CHAUDHURI, M.B.E., late I.M.S., Chief Medical Officer, Lovett Hospital, Ramnagar, Benares State, sends a report of the following case of rat-bite fever, and inquires as to the occurrence of an eruption.

A. H., Mohammedan, a surgical dresser, aged 30, while sleeping in his room on September 7th, 1922, was bitten a little above the left knee externally by a large rat which fell from the ceiling. Blood oozed out for a few minutes, but stopped after a surgical dressing soaked in cold water had been applied. For a week there was neither pain nor fever, and he attended his work as usual. On September 15th the spot bitten suddenly became inflamed and he had a temperature of 99° F. Boric fomentation and ichthyol application brought about temporary relief. On September 24th the swelling, which had become hard, brawny, and carbuncular in appearance, was freely incised, but there was no pus. Fever remained less till September 27th, when the temperature rose again to 103° F., and a shotty and painful eruption made its appearance; it was distributed all over the body, but was most marked on the forehead. A simple diaphoretic was prescribed. Four days later, when the temperature came down to 99° F., neo-salvarsan (0.3 gram) was given intravenously. An hour later he had a shiver which lasted for an hour. After that he not only felt relieved but slept well for the first time since the beginning of the inflammation and fever. The eruption rapidly faded, there being no trace left three days later. He remained free from fever till October 12th; then there was again a rise of temperature which lasted till October 13th. On this date neo-salvarsan (0.6 gram) was given intravenously. The temperature fell rapidly and he made a complete and uninterrupted recovery. It is possible that the eruption was caused by potassium bromide which had been given to induce sleep, but it was not like typical bromide rash.

\* In *The Manual of Tropical Medicine* by Castellani and Chalmers the eruption in rat-bite fever is described as consisting of purple spots often resembling erythema polymorphum. Otherwise the symptoms described above appear to be fairly typical of a mild attack.

#### HICCUP.

DR. R. W. S. CHRISTMAS (South Benfleet, Essex) writes: The correspondence on this subject is very interesting to me. Many years ago (1899) you published a letter of mine on this subject. My case was a most severe one; the patient hiccuped continuously for nine days, and almost died. Most kinds of treatment were tried, but with no good result; even under morphine-atropine, although he slept, the hiccup never ceased. He was seen in consultation and the injections were pushed to full extent. I had used liquor trinitrinæ in many cases of spasmodic conditions with good results, and so thought I would try it in this one: it was really the therapeutics of despair. He commenced first thing in the morning with 1/2-minim doses every hour for three hours; then 1-minim, then 2-minims; to my delight by 9 p.m. the hiccup ceased. There was no return, and the patient pulled through. The week after the publication of my letter Dr. Bezly-Thorne wrote to say that he had tried the same drug in a severe case of hiccup with perfectly good results.

#### CORRECTION.

In the list of books recommended by a correspondent who proposes to sit for the examination in *BRITISH MEDICAL JOURNAL*, March 10th, p. 450, that by Dr. J. W. Mitchell is entitled *The Psychology of Medicine*—not *Medical Psychology*.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 55.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.

Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so accompanied by a reference.

Orders should be delivered, addressed to the Manager, at least 10 days before the first post on Tuesday, and, if not paid for at the time, should be accompanied by a reference. Note.—It is against the rules of the Post Office to receive or forward letters addressed either in initials or numbers.

## A British Medical Association Lecture

ON

## THE DRUG HABIT.\*

BY

W. E. DIXON, M.D., B.Sc., F.R.S.,

READER IN PHARMACOLOGY AND ASSISTANT TO THE REGIUS PROFESSOR  
OF PHYSIC, UNIVERSITY OF CAMBRIDGE.

OUR conscious life may be regarded as a collection and perception of sensory impulses. The ever-changing conscious personality is controlled in adult life by centres which develop only after the age of 10. These later developed centres, such as those of control, judgement, attention, and choice, govern the lower centres, such as those of emotion, so that natural emotions are rarely expressed in adult civilized and cultured life. The repression of sexual emotion is an example, and it is an everyday experience that with age our memory for proper names fails, not because of any loss of function of nerve tissue, but by a repression caused by the exaggerated activity of the higher centres. The subject is bound up with what we have come to term psychotherapy.

But repression, like other higher faculties of mind, is very different in different individuals. Some are so highly reflex, so easily responsive to external impressions, that the associations set loose by any ordinary stimulus cause such a complexity of cerebration that the ordinary affairs of life become a burden. Such people are not phlegmatic and uninteresting, but are rather those possessed of quick perception, acute sensibility, and other higher attributes of mind which go to make up high breeding and culture.

But such a complexity of cerebration cannot continue long; soon it gives place to fatigue, depression, and mental distress. Such people we term neurotics, and they form a class peculiarly prone to succumb to narcotics.

Increased nervous sensibility appears to be a product of civilization and wealth, of indoor life, luxury, and perhaps excessive indulgence in the "satisfaction" of desires. It is difficult to form an estimate of this factor, but attempts have been made to gauge relative sensibility in different nations by estimating the number of women who employed anodynes during normal parturition. The figures obtained were—for the United States 70 per cent., Great Britain 50 per cent., and for Spain and Russia 5 per cent. The figures are interesting in view of the prevalence of drug addiction in the States.

A tendency has shown itself in recent years to classify patients into two groups—those exhibiting an excess of vagotonia, like dogs, and those exhibiting an excess of sympathicotonia, like cats. These two types of people, if they receive the same stimulus, respond differently. The members of the one group may grow pale and their pulse slow, while members of the other may flush and their pulse race. Dogs die in the early stage of chloroform narcosis by vagal inhibition and cats by ventricular fibrillation, probably induced by sympathetic stimulation.

These neurotics always belong to the sympathetic group; they easily weary of the strain and anxiety involved in the fight for existence, and anything that gives them relief from their cares and anxieties is seized with avidity. Now it is these higher faculties of mind which are most responsive to narcotic poisons; they are influenced long before those concerned with movement and ordinary sensation. So that such abnormal people, under the influence of narcotics, lose the exaggerated effect of their normal sensations, and become more like normal people; the everyday trifles and inconveniences of life are no longer exaggerated out of all proportion to their significance, and life, instead of being oppressive and anxious, becomes pleasant and free from worry. Sometimes the very acuity of their intellect is their undoing. Perhaps in a few special instances persons possessed of such vivid sensations may benefit by a narcotic which limits these conflicting impulses by allowing a freer play of the higher mental faculties; certainly the records of De Quincey and Coleridge suggest such a possibility.

I have no doubt that the drug addict is a psychopath before over he becomes addicted, that the ordinary normal man or woman is as unlikely, even with every facility at hand, to become an addict of morphine or cocaine as he is to become a

drunkard. A lady who for a short period worked in my laboratory injected herself daily with morphine until 2 grains were reached for each injection. She gave it up without difficulty, and with no inconvenience after the first day. It is, I suppose, a recognized fact that the drunkard takes to excess of alcohol just as he does everything else that is foolish and wrong—in other words, that drunkenness is one symptom of an abnormal mind.

No one had a more extensive experience as an inspector under the Inebriates Act than Dr. Braithwaite; he is doubtful whether habitual inebriety is ever acquired, and thinks that these people start life handicapped by an abnormal brain. Sir Frederick Mott, at the Glasgow meeting of the Association, expressed similar views. The drug addict is a product of modern civilization, and addiction is a symptom of a diseased mind. For many hundreds of years Christian nations regarded the insane as people possessed of the devil; they were tortured, burned, and subjected to every indignity, and yet insanity continued. Almost the same condition is coming about now with drug addicts. I read that in July, 1921, the New York City Board of Health permitted the incarceration of drug addicts. The police imprisoned several, and the sudden withdrawal of the drug caused the death of one and collapse of several others.

I propose now to mention the substances more commonly used for addiction. Opium or one of its derivatives is the commonest addiction drug; it may be eaten, smoked, or injected. Eating opium or drinking laudanum is rare amongst Europeans, possibly on account of the constipation, the delayed absorption, and the difficulty in obtaining the large supplies necessary. It is, however, not uncommon in India, and its general use led to the Commission of 1895, which reported that moderate indulgence led to no injurious effect and did not shorten life, but that, on the contrary, it tended to ward off sickness and lessened the discomfort consequent on poor food and on malaria and other diseases. Opium is still taken in the fen district of England as a remedy to ward off the ague, a disease which has long ceased to be endemic. In India the opium habit appears to be comparable rather with our smoking than with the morphinist; it is a habit of middle life and advancing years, whilst modern statistics show that 70 per cent. of the European and American morphinists are under 30.

Opium smoking is also mainly an Eastern habit, although it obtained a distinct vogue in the United States of America until it was superseded by the infinitely more objectionable method of injection. The amount of alkaloid absorbed in the smoke is very small, both because the amount of opium used in the pipe is small, and because most of the alkaloid in the opium is destroyed. Absorption is rapid and an immediate effect is produced. Whether this is really due to the morphine I am not prepared to say, since even by smoking all day it would be difficult, if not impossible, to absorb half a grain. The morphine in ten pipes only contains about half a grain, and 99 per cent. of this is destroyed in combustion. After the first few whiffs there is a feeling of elation, followed in the habitué by delightfully languid ease, an exalted sense of superiority, and later by dreamy sleep. The smoker becomes a slave to the habit, and the evil is enhanced—at all events in the West—because the devotee must indulge in his vice in the worst possible surroundings. Opium smoking is the least objectionable form of the vice, because the amount of alkaloid taken is so small, because a strong craving is not formed, and because "cure" is relatively easy, since here we are dealing with a group indulgence, not a secret vice like that practised by the true morphinist. Withdrawal symptoms are never observed.

In Europe and America the alkaloid is usually injected: this is the most pernicious form of taking the drug, and to obtain the requisite relief the devotee must be continually increasing the dose. The amount of morphine injected daily varies greatly; 15 grains is an ordinary quantity for a morphinist to use in the twenty-four hours, though he will double this in the case of any trifling trouble.

Heroin has been used as a substitute for morphine and as an addiction drug since about 1913. This proprietary remedy was easily obtained and was even exported to the East as a cure for opium smoking. The addict often prefers heroin to morphine, since it is less constipating. The average morphine addict has perhaps one or two stools weekly, whereas the bowels of the heroin addict act almost normally. Heroin has no advantages over codeine or morphine, and its use might be forbidden without harming a single genuine patient.

\* Delivered before the East York Division of the British Medical Association, at Hull, on February 9th, 1923.

## EXTENT OF DRUG HABIT.

Reliable statistics are almost impossible to obtain, and such information as we have comes principally from America. Thus the report of the Special Commission of Investigation appointed by the Secretary of the Treasury in the United States in 1918 gives the following consumption per head per annum in 1910:

Austria	...	...	...	about	1
Germany	...	...	...	...	2
France	...	...	...	...	3
United States of America	...	...	...	...	36

Ninety per cent. of this American traffic is probably used for other than medical purposes. The Commission of the Treasury, U.S.A., in 1921 estimated that the country contained at least one million addicts. From all parts of America we find the same tale. In December, 1914, the Harrison Narcotic Law came into existence; it had the support both of the public and the medical profession. In effect this law dictates the manner of practising medicine, and involves many irksome details and much clerical work for the doctor. It includes an army of officials—Federal, State, county, and city—and every grain of narcotic must be accounted for. It has now been actively enforced for seven years, and it is the universal opinion of those best able to judge that it has signally failed in its purpose. The number of addicts and the amount of narcotic consumed is as great or greater than in 1915. I believe the main reason for this is to be found in the fact that the law takes no account of the causes of addiction: the druggist is regarded as a criminal just as were the insane in mediaeval times. Everything can be obtained if the price offered is appropriate to the risk, with the result that smuggling is rampant on the Pacific and Atlantic coasts, from Canada and from Mexico. Distribution is organized by underground channels by means of the so-called dope pedlars. In other words, the law has not altered the supply, but only the distribution of the supply.

Our own less stringent law came into force in September, 1921, and it is too early yet to appreciate its effects. But such drastic laws should make us extremely anxious; they may easily increase the very vice they aim at arresting, for they put a high premium on smuggling, and once the illicit drug dealer obtains a hold on the community an evil is produced infinitely greater than before, when the drugs could be obtained at a fair price through recognized channels.

Much of the increase in drug addiction has without doubt been started in ignorance; opium smoking was regarded as a harmless pastime to be relinquished as desired; the employment of the "white snuff" cocaine served as a stimulant and pick-me-up; and heroin was used as a substitute for morphine with the idea that it was not an opium derivative. There is much evidence that the difficulty in getting alcohol leads people to try any substance which may have a "stimulant effect." But such people are neurotics, their mentality compelling them to search for any remedy to relieve their mental distress. To the normal man opium smoking or cocaine sniffing started in ignorance or in the spirit of adventure or bravado produces little or no pleasurable effect; and although from time to time the process may be repeated I do not believe true addiction ever occurs. The addict always finds it to his advantage to co-operate with the distributor of his drug, and almost never will he give information leading to disclosure of the source of supply.

The chief characteristics of the drug addict are pliancy and disorderliness; they are essentially creatures of impulse. They have little regard for time; appointments are not kept; rules of ethics are scarcely regarded and the conventions are allowed to lapse. When under the influence of their drug the attention can be concentrated for a time and they can write and work, though in a slovenly fashion. The fresh injection gives them a feeling of energy and well-being.

## WITHDRAWAL.

Addicts are held in addiction largely through fear. Prolonged indulgence often fails to give them pleasurable sensations; still they must go on in order to avert the crisis of withdrawal. Their horror of pain, both mental and physical, is an obsession, and contact with the responsibilities of the world they feel is not to be borne.

The symptoms of withdrawal correspond almost exactly with stimulation of those tissues which morphine in medicinal doses depresses. The yawning, sneezing, nausea, vomiting, and mucous secretion result from stimulation of the medulla; the abdominal pains and diarrhoea from stimulation of Auer-

bach's plexus; the twitchings, cramps, circulatory troubles (rapid pulse, arrhythmia), and sometimes even convulsions, and collapse bar... from surgical shock, are due to excessive... cortical cells. Perhaps one of the first and most characteristic effects of withdrawal is a rise in blood pressure from excessive activity of the medulla; this is followed later, at all events in severe cases, by a marked fall in the pressure associated with the collapse. A patient seen with these symptoms, even when in a state of collapse, on receiving an injection of his drug exhibits a transformation almost miraculous; he becomes in a few minutes a relatively normal person. Nitrites in cases of early withdrawal produce much the same effect as morphine on the blood pressure, but do not relieve the mental condition.

Sudden cessation of alcoholic beverages in those who have imbibed too freely for a long period may also lead to withdrawal symptoms, which we term delirium tremens.

The explanation I suggest to account for these withdrawal symptoms is that nerve cells, after prolonged narcosis, on reawakening become hyperexcitable. The contrary effect is an everyday axiom, that stimulation is followed by depression. Another explanation has been suggested by the fact that morphine and cocaine maniacs must be continually increasing the dose to get the necessary effect. This acquired tolerance is at least partly explained by the enhanced power of the tissues to destroy the alkaloid. On this we have decisive evidence. But it is also suggested that this acquired tolerance, this inability of cocaine, morphine, and other drugs to produce their normal action on the brain, is due to some substance which neutralizes the effects of the poison.

Valenti rendered dogs tolerant to morphine, and found that on suddenly stopping the drug the animal showed typical withdrawal symptoms. He alleges that injection of the serum from these dogs into normal dogs caused similar symptoms. This view is now completely disproved. No antibody formation ever occurs in animal or man from the injection of such relatively simple substances as the alkaloids.

## COCAINE.

It has long been known that the Indians in the west of South America, especially in Bolivia and Peru, used coca leaves to chew as a stimulant and narcotic. The Indian uses coca as we use tea and coffee as a stimulant in mental and physical fatigue. Travellers assert that by chewing this leaf they are able to perform long and rapid journeys with less fatigue and without feeling the pangs of hunger and thirst. Experiments in the laboratory, using the ergograph, suggest that these effects are due to cocaine, but experiments by Europeans in the Alps have not been very successful.

Cocaine as an addiction drug is taken either as snuff by the mouth or by injection, and absorption by the nose is as rapid as by injection. Cocaine powerfully excites the central nervous system, inducing a feeling of energy and restlessness. The flagging nerve cells are whipped into activity, and lassitude and fatigue pass; but this is accompanied by clouding of associations and some depression of the central nervous system always succeeds the stage of excitement. Cocaine fascinates by the rapidity with which it relieves exhaustion and dispels gloom and by a delightful sense of mental and physical vigour. Morphine acts not by stimulating, but by depressing sensory nerve cells in the brain, so that fatigue and mental and physical pains are assuaged.

The pure cocaine habit is not very common. The many cases reported in the newspapers were rather cases of users of the drug for specific purposes than cases of addiction. Our men on short furlough during the war were necessarily in an emotional state; anything which helped forgetfulness was seized, and cocaine, used by snuffing, fulfilled the condition. The debauch ended, on the following day there was no desire to repeat the experiment and no craving. Cocaine was used as a rapid and exhilarating intoxicant. Used regularly it might in some instances have led to addiction, but for the most part it did not.

Tolerance can be acquired to cocaine like morphine, but it is less definite and slower in formation; still there are several cases on record in which 100 grains were taken daily. The prognosis in such addicts is better than with morphine, the abstinence symptoms are less severe, and the cocaine can be cut off at once. Cocaine compared with morphine is relatively unimportant in Europe, and there are few cases of cocaine addiction compared with opium. The discomforts caused by cocaine are readily controlled by morphine, and when the

patient learns this the addiction becomes confirmed and of the most serious character.

The other cocaine-like substances which might lead to habit are stovaine, tropacocaine, and perhaps holocaine, though cases of addiction to these are unknown to me.

To some extent fashion or opportunity determines the type of drug used. In New York heroin is used almost entirely, in Chicago morphine is the common narcotic, and in cities with a large coloured population cocaine is in vogue.

#### TREATMENT.

The first and principal fact to remember in treatment is that the addict is not a mentally normal man, and the problem is not so much whether we can temporarily stop the addiction as whether we can educate his mind so that temptation can be withstood—in other words, to alter his character. Simply to control conduct so that choice cannot be exerted is to court disaster.

The following examples will show the effect of custodial care alone.

The Department of Health of the City of New York publishes statistics and details by medical exports of nearly 8,000 cases of drug addicts during ten months; 1,580 received at the clinic were willing to accept treatment and withdrawal of the drug. Those treated were kept six weeks and discharged in good physical condition "cured." In three months a large proportion had already relapsed, in spite of all efforts made to assist them.

Dr. Doane, speaking in November, 1920, stated that there had been treated in the Philadelphia Hospital 3,500 cases of drug addiction, four-fifths of which were heroin and cocaine. These patients were mostly from the lower strata of society. Dr. Doane thought that 3,400 or 3,500 had relapsed. In Los Angeles the Board of Health, with the assistance of the municipal authorities, started a narcotic clinic where addicts got their supply at a nominal price without criminal risk. This system had several advantages: the victims were able to work again; illicit peddling was reduced to a minimum; the addicts became known; but the system was much abused and cures were not effected.

It is generally recognized that of all addicts those that contract the habit as a result of disease are easiest to cure. All addicts desire to be cured but fear the withdrawal symptoms. An addict may beg to give up the habit of his own free will and submit to restraint, but as soon as his wishes are acceded to he will endeavour to render restraint unavailing, and he is so well versed in the literature of the subject that he finds a ready reason for anything he does. He is quite unable to resist an opportunity to cheat if the occasion offers. To ensure even a temporary cure restraint and custodial care are therefore essential.

The chief reason against restraint is that our object is not so much the temporary suppression of the morphine as the cure of the desire for it, and the best way of effecting this is by the re-education of the dormant will.

Under restraint the drug can be gradually reduced, and generally ten days will suffice to bring it down to nil. Some authorities substitute rectal administration for the injections, and some codeine for morphine. Many of these neurotics would do anything rather than diminish their injections; they take a morbid pleasure in injecting something under the skin. During the cure intensive purgation should be carried out. Morphine is the only alkaloid excreted by the alimentary canal, and it is well to get rid of it and prevent reabsorption.

The drug which is perhaps most useful in the treatment of addictions of all kinds is atropine, or, better, hyoscine. Hunger and to a smaller degree thirst are caused by conditions of the stomach, and atropine and hyoscine control the motor nerves to the stomach and intestine. It is more than likely that morphine craving has some association with the stomach. Many other drugs are, however, employed: nitrites and sparteine to lower blood pressure during the withdrawal symptoms, alkalis to combat the dyspepsia, and such drugs as valerian or asafoetida to produce a profound psychical impression. Dr. Quincey found much benefit from valerian. To effect a cure the patient must be made to live a methodical life, to partake of temperate meals, and to observe orderliness in everything, all of which are loathed by the neurotic and morphinist.

In conclusion I desire most strongly to protest against the modern tendency to regard these people as criminals; they are and should be regarded and treated as mental cases,

addiction being the prevalent symptom at the time. The Harrison Narcotic Law has proved a failure in America, yet our own authorities have legislated on parallel lines, and time only will show whether the cure is not worse than the disease.

Since this lecture was delivered an amending bill to the Dangerous Drugs Act of 1920 has been read a second time in the House of Commons and referred to a Standing Committee. It proposes that these narcotic drugs shall be purchased only by registered medical practitioners in actual practice, whatever that may mean. I suppose all registered medical men are in actual practice, though many of us are not in practice for profit. Very large quantities of morphine and cocaine are used by the various chemical and pharmacological laboratories throughout the kingdom. Medical students may be required to detect morphine in solution and to investigate its properties on isolated mammalian tissues. Alkaloidal chemistry without morphine and cocaine is indeed unthinkable.

The second objectionable provision is that the practitioner may not prescribe for himself; horrible penalties are attached to infringement of both these provisions. Almost one is tempted to ask, Can legislators be so foolish as to attempt to pass laws directly concerning medical men which are against the whole feeling of the profession and which are calculated to cause intense resentment? If the drug traffic is to be exterminated then all our hope should be centred on the registered practitioners in this country, and to make bad law by legislating for a hard case or two will do infinitely more harm by alienating the majority of the profession than the mite of good.

### MAN'S POSTURE: ITS EVOLUTION AND DISORDERS.

GIVEN AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

BY

PROFESSOR SIR ARTHUR KEITH, F.R.C.S., F.R.S.,  
CONSERVATOR OF THE MUSEUM.

[Abstracts.]

#### LECTURE III.—THE POSTURAL ADAPTATIONS OF THE SHOULDERS AND THORAX.

At the end of a long day's tramp most of us have become aware of a vague aching pain in the region of the shoulders. Nor need we feel surprise when we remember the heavy burden we have had suspended from our neck throughout the day—the load represented by the upper extremities. In a man of average weight the shoulders and arms represent a burden of about 20 lb. They are suspended from the cervical and upper dorsal regions of the spine—chiefly by the trapezius muscles and particularly by the fibres inserted in the neighbourhood of the tip of the shoulder. Then there is another composite sheet of muscle, made up of rhomboid and serrate parts, which is also concerned in maintaining the shoulders in position. By the rhomboid muscles the vertebral base of the scapula is supported from the lower cervical and upper dorsal spines; by the serratus magnus the base of the scapula is steadied on the side of the thorax because that muscle springs from the eight upper ribs. We may look on the rhomboids and serratus magnus as forming a continuous muscular sheet passing from spines to ribs; within it the base of the scapula is embedded and steadied. The levator of the angle of the scapula, originally part of the serratus sheet, is also concerned in balancing and supporting the shoulder from the neck. Now and again, once in a hundred subjects, we see another muscle helping in the support—the levator claviculae. It is strange that man is the only one of the higher primates in which this muscle has become vestigial; it is also noteworthy that in the chimpanzee this muscle is small and tends to disappear. The sterno-mastoid and pectoral muscles also play a subsidiary part in supporting and balancing the shoulder.

#### SUSPENSORY MECHANISM OF THE SHOULDERS.

When we stand or sit a postural reflex mechanism is brought into action which keeps the shoulder muscles constantly at work until we lie down again. How complex this

mechanism must be inferred from the observation of Dr. Gordon Holmes; he noted that when the cerebellum was injured on one side, the shoulder of the same side had dropped downwards and forwards, because the postural tone of the supporting muscles was partly lost. Professor Wingate Todd<sup>1</sup> has stated that, in passing from infancy to adult life, a progressive dropping of the shoulders takes place; both outer and inner ends of the clavicle descend, but the descent is greatest at the outer ends.

#### DROPPING OF THE STERNUM AND RIBS.

The falling of the shoulders is not an isolated occurrence, but part of a process in which the whole thoracic region participates. This dropping or ptosis, which may be recognizable by the end of childhood, becomes clearly evident by the end of the third decade. The sternal ends of the ribs and the sternum itself come to take up a respiratory position at a level of one or more vertebrae lower down than in childhood. The level of the domes of the diaphragm descends, the oesophagus becomes elongated; the lateral segments of the ribs more oblique in position, the angles formed by the ribs with their cartilages more oblique. With the descent of the ribs the back-to-front diameter of the thorax is necessarily diminished; Wintrich found that in people who had passed middle life the front-to-back diameter of the thorax had become reduced by 33 mm. in men and 26 mm. in women. The diminution in side-to-side diameter is much less.<sup>2</sup> An exaggerated degree of this normal dropping of the shoulders, with a diminished or inspiratory poise of the thoracic walls, must be regarded as a result of an exhaustion, or partial exhaustion, of the postural muscles which support the shoulders and ribs when the human body occupies the upright position.

#### PRESSURE ON THE BRACHIAL PLEXUS.

If the tonus action of the supporting muscles of the shoulder should fail, then a strain must fall on the brachial plexus, particularly on the lower cord as it crosses the first rib. This is especially likely to be the case if the lower cord has to cross a rib attached to the seventh cervical vertebra. Bramwell and Dykes state that not more than 5 or 10 per cent. of cervical rib cases develop symptoms of nerve pressure. Carriers of cervical ribs are certainly more liable to pressure symptoms than those of normal development; the essential circumstance which gives rise to symptoms of plexus pressure is not the presence of a cervical rib, but a failure or partial failure of the mechanism evolved for the support of the shoulders in the erect posture.

#### A LATE PRODUCT OF EVOLUTION.

The postural mechanism for the maintenance of man's shoulders is a human character of late evolution; it must have come with the adaptation of his lower limbs as the sole organs of support and progression. Man is a flat-backed and broad-shouldered animal; his shoulder blades are placed on the back rather than on the sides of his chest. In these features, however, man does not differ from other members of the orthograde group of primates—the gorilla, chimpanzee, orang, and gibbon. He differs from them in this circumstance—that in the climbing, moving arboreal anthropoid the arms and shoulders have to sustain or help to sustain the weight of the trunk, whereas in man the trunk has to sustain the weight of the shoulders and arms. In the anthropoid shoulder all the essential structural features of the human shoulder are already present; we have only to suppose the perfecting of a supporting reflex postural mechanism for the shoulders and a reduction in the length of the arms to realize how the anthropoid condition might become human. Suspension of the upper extremities is a late product of evolution and must be regarded as a human characteristic.

#### SUPPORTS OF THE PRONOGRAD THORAX.

In tracing the evolutionary stages which led on to the human spinal column we found that the great break in the series came not between the human phase and the great anthropoid phase, but between the lowest of the orthograde apes—the gibbons—and the highest of the pronograde monkeys. When we seek for the stages which lead on to the human position of shoulders and shape of thorax, we find the real break in the series again occurs at the passage from the pronograde to the orthograde form. If we would understand the changes involved in the evolution of the human shape of thorax and the human mechanism of respiration, we

have to go back a long way in our geological history and formulate a theory which will account for the origin of the orthograde gibbon. One has to note particularly the manner in which the thoracic part of the body is supported on the arms or forelimbs of pronograde monkeys. The back is narrow and the shoulders are set by the side of the thorax, coming close together on the back almost as in a dog. The ventral or sternal aspect of the thorax is also narrow; the body of the sternum itself is a jointed rod. The lateral walls of the anterior part of the thorax are flattened and the scapulae are placed against them. By a series of muscular slings or hammocks the weight of the body is transferred to the upper limbs and shoulder girdles. Chief of these muscular slings or supports are the right and left great serrate muscles, which, rising from the lateral aspect of eight anterior ribs, ascend to be inserted to the vertebral borders of the shoulder blades. The two levator muscles to the angles of the scapulae continue the serrate hammock into the neck; they arise from all the transverse processes of the neck. The rhomboid sheet binds the vertebral border of the scapula to the spinous processes of the neck and upper dorsal region; the trapezius muscles also assist. A secondary muscular hammock is formed by the right and left pectoral sheets (pectoralis major, pectoralis minor, pectoralis externus). They pass from the sides of the sternum and adjacent ends of the costal cartilages to find insertions to the upper ends of the humeri. The flattening of the chest from side to side and the approximation of the shoulders are adaptations to the pronograde manner of progression and of thoracic support.

#### SHAPING OF THE ORTHOGRAD THORAX.

Many occasions in the arboreal life of a monkey arise when branches have to be clutched by the hands and the whole weight of the body supported from the arms. The muscular slings which attach the shoulder girdle to the body in these circumstances take on a new action; the thorax of the animal now becomes compressed between the ventral and dorsal muscular slings and so tends to be flattened in a back-to-front direction. Now this method of arm suspension, which is only occasional in pronograde primates, has become habitual in gibbons—the arms are the main means of support and progression. The thorax has become flattened before and behind, its sides are rounded, the ribs are drawn up as if they were in a position of extreme inspiration. The pectoralis major—a main part of the muscular sling—has no longer a mere sternal origin as in pronograde apes, but has extended its base of attachment upwards to the clavicle and outwards on the fifth and sixth costal cartilages, almost to the bony ribs. The origin of the pectoralis minor has become shifted from the side of the sternum outwards almost to the costo-cartilaginous junctions. The trapezius, rhomboids, and latissimus dorsi form the dorsal part of the muscular sling for supporting the weight of the body from the arms. In pronograde monkeys the latissimus arises merely from the spinous processes of the back, but in gibbons its origin has been extended forwards, so that it has a fascial origin from the iliac crest and direct muscular origins from the three or four lower ribs. The serratus magnus, now strong and highly specialized, plays an important rôle as a muscular sling. It exerts a traction on the side of the thorax tending to increase the lateral convexity of the ribs and the side-to-side diameter of the thorax. The shoulder, instead of being placed laterally as in pronograde forms, becomes drawn outwards and backwards and thus comes into being the broad-shouldered figure which characterizes all orthograde forms, including man.

#### ARE THE EFFECTS OF USE INHERITED?

Some thirty years ago I was of opinion that there was no other way of explaining the peculiar features of the gibbon's thorax except by supposing that some pronograde primate had adopted a brachiating habit of progression and that the chest, by inheritance of the effects of use, under the suspensory action of the shoulder muscle slings, had become transformed from a pronograde into an orthograde type. This idea I have abandoned for the following reasons: No alteration in use can cause a migration in the origin or insertion of a muscle—such as we see in the attachments of the muscles directly concerned in slinging the thorax from the shoulder in orthograde apes. During the period of development we see the process of muscular migration actually taking place; it is a developmental process carried out by a force the nature of which we do not yet comprehend, but we cannot conceive a way by which it could be influenced by inheritance of effect. Further, we note, particularly in certain kinds of pronograde monkeys,

tendencies for certain muscles to migrate in a certain direction—tendencies which have become exaggerated and take place regularly in orthograde apes. We see a process, which is tentative and incipient in more primitive apes, become fully effective in the later and more specialized orthograde forms. In such manifestation we have clearly to do with a developmental or growth mechanism; it is one which affects not only the attachments of the upper limbs to the body and the shape of the thoracic walls, but involves a simultaneous alteration of all the structures concerned in respiration—lungs, bronchi, trachea, pleura, diaphragm, the great blood vessels in the heart itself. It is these latter structures which now demand our attention.

#### EVOLUTION OF THE FLAT BROAD STERNUM.

Amongst the most remarkable changes which took place during the evolution of the orthograde posture was the transformation of the sternum. In the higher pronograde monkeys the breast bone, all save its first part or manubrium, is made up of rod-like segments, usually five in number. In all orthograde primates—the gibbon, orang, chimpanzee, gorilla, and man—the sternal segments ultimately become fused and form a stout, plate-like structure—the short sword sternum. The widening and stiffening of the sternum has greatly strengthened the anterior wall of the orthograde thorax. It is easy to see why the sternum should become strong and plate-like. When the upper limbs become used for the purposes of suspension and prehension greater stresses must fall on the thorax—particularly the parts to which the pectoral muscles are attached. Although the primary reason for the transformation of the sternum is connected with posture and locomotion, such a complete change in the structure of the sternum must have reacted on the mechanism of respiration. It led to the development of upper thoracic or chest breathing.

#### THE IMPORTANCE OF THE INTERCHONDRAL FACETS.

Often the consideration of minor points of structure will guide the anatomist towards important conclusions. Medical men must often have noted the articulations between the fifth and sixth and sixth and seventh costal cartilages; the upper cartilage throws down an elbow, which comes into contact with the cartilage below; at the point of contact there is a synovial facet. In only three animals do we find these elbows of cartilaginous contact—man, the gorilla, and chimpanzee. They are not present in either gibbon or orang; in them the suspensory use of the upper limbs has become predominant in locomotion, and in consequence they have become "pigeon-chested"; nor are they present in pronograde apes or monkeys. We obtain a clue to the functional meaning of the intercartilaginous facets if we consider the mode in which the diaphragm acts in pure thoracic breathing. The diaphragm then exerts its power, not in depressing the abdominal viscera but in raising the anterior or ventral ends of the ribs to which it is attached—namely, the lower six. Through the cartilaginous heels on the fifth and sixth cartilages its power is extended to the solid plate-like sternum, which it also raises. As the sternum is elevated it will be found that a bending or flexion takes place at the joint between the body of the sternum and the manubrium or presternum. Further, we note in the highest of the orthograde primates, particularly in the human thorax, that the first pair of ribs and manubrium become more and more welded together to form a single functional structure, for which I have proposed the name of "thoracic operculum." The thoracic operculum is set obliquely; it is hinged behind to the first dorsal vertebra; it rests in front on the body of the sternum; it is almost stationary if the respiratory movements are purely of the abdominal type, as in pronograde apes; it becomes a freely moving structure when respiration is of the thoracic type.

#### RISE IN IMPORTANCE OF THE APICAL REGION OF THORAX.

That the evolution of the orthograde posture gave an enhanced respiratory importance to the upper thorax is seen from another line of evidence. The straight muscles of the abdomen are the flexor muscles of the spine. In the thoracic region they are attached to the ventral ends of ribs; behind, to the ventral or pubic end of the pelvic girdle. These structures serve as powerful spinal levers; through these levers the straight muscles are more than a match for the extensors of the spinal column. Now, in the human body, as in that of all orthograde primates, the straight muscles take hold of the fifth, sixth, and seventh costal cartilages. In the older pronograde

forms the straight muscles extend their origin forwards to the whole length of the sternum and to the first pair of ribs—as is the case in all the more primitive vertebrate mammals. With the evolution of the orthograde posture the origin of the straight muscles was withdrawn from the four upper ribs, thus setting them free for a new kind of movement. This retreat of the straight muscles was accompanied by that of the external obliques and *scalenus medius*. Thus all the structural transformations which occurred during the evolution of the orthograde posture led to the freedom and increased respiratory importance of the apical region of the thorax. We shall see that these changes in the walls of the thorax were accompanied by corresponding modification of the apical region of the lung.

#### POSTURAL CHANGES WITHIN THE THORAX.

Up to this point our attention has been concentrated on the modifications of the thoracic wall involved by the change from a pronograde to an orthograde posture. We are now to enumerate, as briefly as possible, the structural alterations which took place within the thorax. The dissection which best suits our purpose is one often practised by human anatomists; extensive windows are cut in the lateral walls of the chest and through these the root of each lung is exposed, then cut through and the lungs removed. The mediastinal wall is thus exposed, and we can note the exact form of each pulmonary cavity. When such a dissection is made of one of the commoner pronograde monkeys, we are at once struck by the oblique position in which the diaphragm is set; its domes slope from the lower end of the sternum towards the eleventh pair of ribs. If we make a similar dissection of a gibbon we find the diaphragm arranged much as in man; the central tendon has become cordiform in shape and the domes of the diaphragm nearly horizontal in position. The flattening of the dorsal and ventral wall of the orthograde thorax has altered the contour of the diaphragm, giving it a wide cordiform shape. The chief structural changes concern the muscular fibres of the crura of the diaphragm. In pronograde monkeys the crural or spinal fibres are widely separated from the costal fibres by an interval filled by a fibrous membrane. In the gibbon, as in all orthograde forms, the fibrous interval is obliterated by the outward migration of crural fibres; the origin of the outer fibres has become shifted from the bodies of the upper lumbar vertebrae, over the sheaths of the *psaos* and *quadratus lumborum* muscles. We have here another example of muscular migration playing a part in an evolutionary movement.

#### Fixation of the Heart.

When we compare the thoracic dissections of the monkey and gibbon we see that the orthograde posture has entailed an alteration in the position and also in the fixation of the heart within the thorax. The point which particularly catches our attention in the monkey's thorax is that the inferior vena cava, instead of at once entering the pericardium on appearing above the diaphragm, as it does in man and in all orthograde apes, has a course of some two inches before it enters the base of the heart. Only the apex of the pronograde heart comes in contact with the diaphragm. Between the heart and diaphragm passes a sinus or diverticulum of the right pleura; the mouth of this subcardiac sinus lies internal, or medial, to the inferior vena cava; it is occupied by the azygos lobe of the right lung. When the diaphragm contracts the azygos lobe is distended, this inspiratory descent being accompanied by a stretching of the highly elastic inferior vena cava. In the gibbon the heart is bound more closely to the diaphragm, but an azygos lobe and a reduced subcardiac sinus are clearly recognizable. In the great anthropoids and man the base of the heart has become firmly bound to the diaphragm; in all of them a vestige of the azygos lobe of the right lung and of the subcardiac sinus are unmistakably present. There is no better proof of man's pronograde ancestry than the evidence he carries in his right lung.

#### Development of the Apical Region of the Lung.

As the orthograde heart settled on the upper surface of the diaphragm it lost the tapering form seen in pronograde animals, and assumed the blunt conical form we are familiar with in man's body. But why does the base of the heart become so closely attached to the diaphragm in orthograde forms? It is because of the increased development of the apical region of their lungs; the suprardicular parts of the lungs can be thoroughly aerated only if the roots of the lungs

participate in the respiratory movements of the diaphragm. The heart and pericardium are fixed to the roots of the lungs; in orthograde forms the pericardium becomes bound to the diaphragm.<sup>3</sup> Thus with the evolution of the great anthropoids there came about a new relationship between the diaphragm and roots of the lungs; the central tendon of that muscle became yoked to the roots of the lungs through the pericardium. In the chest of man this relationship is even more intimate than in anthropoids. For the proper aeration of the apical part of man's lungs diaphragmatic movements are essential.

#### Other Respiratory Changes.

It would take us too far afield were we to analyse all the intrathoracic changes which mark the evolution of the orthograde posture. The arch of the aorta and the manner in which it gives off its great branches became altered; the human arrangement is linked on to the pronograde type by a series of intermediate stages seen in the great anthropoids. The lung assumed a conical shape, with the wide and hollow diaphragmatic base with which we are familiar in human anatomy. The fissures of the lung become less deep; they have almost disappeared from the lungs of the orang. The apical lobes become larger, the inferior lobes, particularly the parts which fill the hinder and lower recesses of the pleural cavities, smaller. The distribution of the bronchial tree was changed, the apical supply becoming increased.

#### SUMMARY.

It will thus be seen that the evolution of the orthograde posture was attended by a structural revolution in all those parts which are concerned in setting up a tidal flow of air to the lungs. Ribs, vertebrae, sternum, body wall and spinal muscles, diaphragm, pleurae, lungs, and heart underwent a simultaneous and harmonious adaptational transformation. To account for such a structural revolution we must postulate a much more elaborate mechanism controlling developmental processes than any we have knowledge of as yet. Further, it is evident that the square shoulders, the flat back, the wide chest, the cordiform diaphragm, we are familiar with in man's body, are of ancient origin, having been evolved with the appearance of the earliest of orthograde primates.

## The Goulstonian Lectures

ON

## THE NATURE OF ARTERIO-SCLEROSIS.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS  
OF LONDON

BY

GEOFFREY EVANS, M.D. CANTAB., F.R.C.P. LOND.,  
ASSISTANT DIRECTOR, MEDICAL UNIT, AND ASSISTANT PHYSICIAN,  
ST. BARTHOLOMEW'S HOSPITAL.

### LECTURE III.—CAUSATION OF DIFFUSE HYPERPLASTIC SCLEROSIS.\*

THE description of diffuse hyperplastic sclerosis formed the subject of the first lecture; the process concerned in its production and the opinion that it was one of inflammation was presented in the second; the matter of its causation remains for consideration.

Since diffuse hyperplastic sclerosis has not been produced experimentally only clinical evidence on causation is available, and before this is discussed the clinical signs of diffuse hyperplastic sclerosis need to be established. The clinical diagnosis is nearly always a matter of inference, since there is rarely the opportunity for microscopical examination of a piece of tissue; though the study of retinal vascular disease holds out the prospect of the accurate diagnosis of diffuse hyperplastic sclerosis during life the correlation of ophthalmoscopic findings with histological lesions is not as yet complete. The clinical picture can be established, however, on the basis of the naked-eye *post mortem* indications of the presence of the lesion.

### NAKED-EYE POST-MORTEM EVIDENCE OF DIFFUSE HYPERPLASTIC SCLEROSIS.

The identity of diffuse hyperplastic sclerosis as an affection of the larger vessels has not been established, hence it can only be recognized by microscopical examination of tissues cut fresh or suitably embedded to retain their fat. Its presence is inferred from the appearance of thickening of the smaller arteries, particularly of the kidneys and spleen, and the vessels are seen to protrude like little quills (in the words of Hilton Fagge) on the cut surface of these organs. When there has been a raised blood pressure during life the walls of the larger arteries such as the splenic and iliac arteries are obviously thickened, and the hypertrophied media shows as small transverse ridges on the inner surface of the vessel wall.

Cardiac hypertrophy, especially affecting the left ventricle, when not due to disease of the heart and lungs, is termed "idiopathic hypertrophy" for the sake of present convenience, and it is the most important evidence, though not proof, of diffuse hyperplastic sclerosis. Its significance in this respect has been tested by two lines by inquiry. In the first place, an analysis of twenty consecutive years of medical *post-mortem* records of St. Bartholomew's Hospital<sup>1</sup> showed that idiopathic cardiac hypertrophy of more than 15 oz. weight was significant of cardio-vasculo-renal disease. Thus the records of the great majority of cases with idiopathic hypertrophy showed death due to cerebral haemorrhage, heart failure, or uraemia; or when death was due to other cause the records made reference to arterio-sclerosis or some form of renal sclerosis. The few exceptions included a small group of cases of pernicious anaemia (Cabot has also called attention to cardiac hypertrophy in this disease), a few cases of alcoholism,<sup>2</sup> and obese heart. In the second place, I have found diffuse hyperplastic sclerosis in all cases of idiopathic hypertrophy that I have examined microscopically. The hypertrophy of the heart and media of the arteries is to be regarded as a compensatory phenomenon, physiological expressions of increased activity during life. The only essentially pathological sign of diffuse hyperplastic sclerosis is renal sclerosis in one of its several forms—a matter that will be referred to later. In short, the essential *post-mortem* picture of diffuse hyperplastic sclerosis is limited to the cardio-vasculo-renal system; it consists of left ventricle hypertrophy, the appearance of medial thickening, and renal sclerosis. This picture is often dominated by one of the complications or sequelae of vascular disease, such as cerebral haemorrhage, thrombosis, heart failure, or septicæmia; it may also be one aspect of a coincident condition, such as nephritis when death is due to uraemia, and it is often overlooked when death is due to an intercurrent disease such as pneumonia or cancer.

### CLINICAL PICTURE OF DIFFUSE HYPERPLASTIC SCLEROSIS.

*Post-mortem* evidence establishes the clinical diagnosis of diffuse hyperplastic sclerosis on idiopathic cardiac hypertrophy and renal sclerosis. The clinical diagnosis of the former is not without difficulty, since heart disease, particularly myocardial disease, is often difficult to exclude. From a comparison of blood pressures taken during life and heart weight determined after death a close relation has been established between raised systolic pressure and idiopathic hypertrophy. The direct relation shown in my first paper on arterio-sclerosis<sup>1</sup> has not been borne out by a series of 32 cases collected since. The two series are not, however, directly comparable, since the second series was merely compiled from clinical notes and *post-mortem* records. Other factors than mere increase in blood pressure are concerned in determining the degree of cardiac hypertrophy. Of the 32 cases of idiopathic hypertrophy that form my second series (heart weight more than 15 oz.) the systolic blood pressure during life was 180 mm. Hg or over in 84 per cent., and was 170 mm. Hg or over in 94 per cent. These cases furnish further evidence of the association of raised blood pressure and idiopathic hypertrophy, which is already generally accepted. In choosing an arbitrary figure of systolic pressure as having a pathological significance it is very necessary to take a conservative line, since the blood pressure is liable to a considerable variation in health,<sup>3</sup> and in conditions of fatigue, excitement, pain, dyspnoea, and the like, but my experience has been that the systolic pressure does not reach 180 mm. Hg under such conditions; and having regard to the relation of diffuse hyperplastic sclerosis on the one hand, and of a systolic blood pressure of 180 mm. Hg to idiopathic

\* Abstract of lecture delivered on March 15th.

cardiac hypertrophy on the other hand, I believe that a systolic pressure of this level is definite clinical evidence of diffuse hyperplastic sclerosis, provided always that the reading is taken under good conditions. In outline my view is that the clinical signs of diffuse hyperplastic sclerosis are idiopathic cardiac hypertrophy (standard being 15 oz. weight *post mortem*) and a raised systolic pressure (180 mm. Hg). There is no need to complete the clinical picture, and I will pass on to consider the various diseases in which these two signs are present.

### 1. Hyperpiesia.

Sir Clifford Allbutt<sup>1</sup> introduced this term to define a group of cases of which the outstanding features are a persistently raised blood pressure with cardiac hypertrophy but without kidney disease; thus far the description applies to a clinical condition, but Sir Clifford Allbutt uses the term to define not merely a condition but a disease—one that may respond to treatment and recover, or alternatively pursue its own course and terminate in death. In this latter event it preserves its identity as a morbid series that does not pass through or into Bright's disease; it is marked by the absence of such classical signs as an earthy complexion, a pronounced secondary anaemia, and also by the condition of the urine, which, though it may contain a few hyaline or granular casts or a small quantity of albumin, does not in hyperpiesia become pale in colour or low in its specific gravity; neither does it contain red blood cells or epithelial casts, unless it is complicated by marked venous congestion as a result of heart failure. In view of the relation of cardiac hypertrophy and raised blood pressure to diffuse hyperplastic sclerosis, and since these are the cardinal signs of hyperpiesia, I maintain that the clinical expression of diffuse hyperplastic sclerosis is hyperpiesia.

The connexion between hyperpiesia and its vascular lesion is so close that it is commonly regarded as one of cause and effect. The older view that the vascular lesion is responsible for the hypertension is no longer tenable.<sup>4</sup> The present opinion is that hypertension is the cause of arterio-sclerosis, an opinion that is expressed by Sir Clifford Allbutt in his distinction of a hyperpietic form of arterio-sclerosis. This opinion has received support from the work of Jores, reinforced by his interpretation of his histological findings (Lecture II). It is also supported by the record of cases of hypertension without demonstrable vascular lesions after death<sup>5,6,7</sup>; again, the clinical fact that hyperpiesia is a recoverable disease, balanced against the opinion that arterio-sclerosis is a permanent pathological change, a final event from which recovery cannot occur, is urged in the same sense; and lastly, there is the circumstance that blood pressure measurements are taken during life and vascular lesions are studied later after death. Such evidence as this does not bear critical examination. It is not certain that diffuse hyperplastic sclerosis is a permanent pathological change, or if it is the body may be able to so adjust itself that the patient recovers from hyperpiesia though his arterio-sclerosis persists. Further, to establish a sequence in time between the development of hypertension and diffuse hyperplastic sclerosis does not establish the relation of cause and effect since both may result from the action of a common cause, and the difference in time of their development may depend on the longer time required for the development of a structural lesion as compared with a functional lesion.

Hyperpiesia may be dependent upon a disturbance of vascular function due to the activity of a pressor substance in the sense postulated by Dr. Batty Shaw,<sup>8</sup> and Krogh's work<sup>9,10</sup> on capillomotor activity throws a new light on the mechanism set in motion at this stage of the disease. A similar problem is present in Raynaud's disease when vasoconstriction is so persistent and severe that gangrene of a distal part results without the occurrence (according to Leo Buerger) of a demonstrable vascular lesion; but in the only case of Raynaud's disease that I have examined there was an extreme degree of arterio-sclerosis in the digital arteries of a finger that had to be amputated for gangrene.

While there is no adequate clinical evidence for the opinion that mechanical strain is a cause of diffuse hyperplastic sclerosis, pathological evidence is contrary to such a view. Jores's views on the subject fall to the ground with the failure of his distinction between regenerative and hyperplastic layers in the thickened intima of diffuse hyperplastic sclerosis. The actual lesion in the arterioles, the endothelial cell proliferation and subsequent fatty degeneration, is not open to explanation in terms of increased blood pressure. Fatty degeneration is

an expression of deficient oxidation, and a mechanical strain that shows itself in this weakening of the vessel wall can hardly be responsible at the same time for the increased tissue activity shown by proliferation of the endothelial cells of the perfect form and staining seen in these vessels. Mechanical strain fails equally as a working hypothesis in regard to the distribution of the lesion, for it does not explain the relative incidence of the lesion on the several organs of the body; it is no explanation of its major incidence on the kidneys and spleen, its common presence in the brain, pancreas, liver, and suprarenals, its relative rarity in other organs, and its absence from skeletal muscles and heart. The theory of increased blood pressure fails to account for the development of diffuse hyperplastic sclerosis, and it is concluded from the evidence at present available that the cause of diffuse hyperplastic sclerosis is the same as that of hyperpiesia.

### 2. Renal Sclerosis.

There is some degree of renal sclerosis in all cases of diffuse hyperplastic sclerosis, and there is some vascular lesion in all cases of renal sclerosis. Apart from polycystic kidneys, tuberculous and obviously syphilitic kidneys, calculous and other forms of pyelonephritis, renal sclerosis is divisible into two main groups according to the distribution of the lesion in the organ.

*Group 1: Chronic Nephritis.*—The lesion is diffuse; though not uniform it is widely distributed throughout the organ. The essential lesion is a glomerulitis, shown by proliferation of the cells of Bowman's capsule, or at a later stage by adhesion of the parietal and visceral layers of the capsule. The constant lesion, as in all forms of renal sclerosis, is an increase of fibrous connective tissue. Taken as a whole, and in their more chronic forms, these kidneys tend to be associated with diffuse hyperplastic sclerosis and cardiac hypertrophy. The association of diffuse hyperplastic sclerosis with chronic nephritis is best illustrated by its occurrence in children, of which I have recently published four cases in detail<sup>11</sup>; from another point of view it is illustrated by statistical evidence of cardiac hypertrophy in its relation to kidney disease (see Ref. 1, p. 248). The lesion in chronic nephritis is without doubt inflammatory, and its association with diffuse hyperplastic sclerosis has been brought forward as further evidence in favour of the inflammatory nature of the vascular lesion. The vascular lesion may develop to an extreme degree, so that the parent arteries are almost completely obliterated; in other cases of extreme renal disease the vascular lesion may be relatively slight and limited to the kidneys. Clinically there may be a history of acute nephritis or of oedema of the renal type. The symptoms of which the patient complains are those commonly regarded as uraemic, of which the more important are headache, gastro-intestinal disturbance, and disturbance of vision due to albuminuric retinitis. In well marked cases there is pallor of the face; in severe cases a muddy complexion and secondary anaemia; the urine contains red and white blood corpuscles and cell casts, and at a later stage it is pale in colour and of low specific gravity. Sometimes there are no cells or casts in the urine. Puffiness of the face is common; cardiac oedema is more frequent than renal oedema. Hypertension and cardiac hypertrophy are characteristic but not essential features of the clinical picture.

My interpretation of the association of diffuse hyperplastic sclerosis and chronic nephritis is that both lesions are provoked by the same cause or causes, and the solution of the etiology of chronic nephritis will solve the etiology of diffuse hyperplastic sclerosis (see also Ophüls, loc. cit., p. 95). This view has lately received support from the study of the histology of war nephritis in the early stages of the disease. Herxheimer<sup>12</sup> has recorded that the earliest lesion is of the endothelial cells of the glomerular tufts; initially it is limited to occasional loops of occasional glomeruli; soon the whole or the greater part of the tuft is affected and the great majority of all glomeruli are involved. Inflammatory reaction in the cells of Bowman's capsule, the typical lesion in nephritis, is a subsequent event.

*Group 2* includes all kidneys in which the lesion is partial, being limited to wedge-shaped areas with their base on the surface and their apex pointing to the cortico-medullary zone. These areas correspond to depressions on the surface of the organ: when they are small the surface is almost smooth (as in the hyperpietic kidney); when they are large and deep the surface is coarsely granular (as in true chronic interstitial nephritis). The areas consist of fibrous tissue, damaged renal parenchyma, and more or less small cell infiltration. The

intervening tissue is relatively normal and the parenchyma may be hypertrophied. On account of the presence of normal tissue these kidneys retain their colour (which depends largely on their capillary blood content), in contrast to the kidneys of chronic nephritis in which the lesion is diffuse and the colour pale.

*Subgroup (a): True Chronic Interstitial Nephritis.*—Histologically there is evidence of active inflammation in the presence of glomerulitis, similar to that seen in chronic nephritis, and small cell infiltration out of proportion to the degree of glomerular tuft damage. The differential diagnosis of these cases clinically from chronic nephritis may be impossible. As a general rule they occur after the age of 35, whereas chronic nephritis is commoner before 35. The most obvious aspect of the clinical picture is cardio-vascular disease, the symptoms being those of heart failure, or simulating hyperpiesia, or sometimes they are purely vascular, as in gangrene of the toes. The renal aspect of the case, in its symptoms, facies, or urinary findings, is a less prominent feature than the cardio-vascular aspect, but to the extent that it is present it is of the same kind as in chronic nephritis. The changes in the fundus oculi are those of arterio-sclerotic retinitis,<sup>13</sup> in contrast to albuminuric retinitis in chronic nephritis. The most marked cases of diffuse hyperplastic sclerosis are found in this subgroup, and they are associated with the highest systolic blood pressures. These cases with their definitely inflammatory renal lesion are further evidence of the inflammatory nature of diffuse hyperplastic sclerosis and point to a common etiology of it and chronic interstitial nephritis.

*Subgroup (b): True Arterio-sclerotic Kidneys.*—This subgroup is further subdivided into two types, according to whether the accompanying vascular lesion is of the type of diffuse hyperplastic sclerosis or senile arterio-sclerosis.<sup>14</sup> This classification, which I suggested in 1921, seems to hold good in the light of material examined since, and has been recently followed by Professor Shaw Dunn.<sup>15</sup> Chronic nephritis and chronic interstitial nephritis can be similarly subdivided according to the type of the vascular lesion present, but it is not necessary for the present purpose. The essential histological feature of the kidneys in Subgroup (b) is the absence of definite signs of inflammation, apart from the vascular lesion, in these kidneys; the glomeruli undergo hyaline degeneration and fibrosis; there is no proliferation of Bowman's capsule; there is little small cell infiltration, and the degree of glomerular tuft damage. Clinically these cases have no renal aspect, and do not suggest the picture of Bright's disease in any of its well recognized forms. The renal lesion is only evident in a trace of albumin in the urine; the urine is of good colour and normal specific gravity. Of the two types included in this subgroup the one in which there is diffuse hyperplastic sclerosis is the more important, for it is associated with raised blood pressure and cardiac hypertrophy, and is hyperpiesia. Microscopically the kidneys are relatively normal in appearance, their surface is smooth, or very finely granular, or they may be marked by scars like old infarcts. On section they are a little firmer than normal, and the vessels are unduly prominent. I suggest the name "hyperpietic kidney" for this type of renal sclerosis, and its significance in respect to the etiology of diffuse hyperplastic sclerosis has been already discussed under hyperpiesia.

This slight review of the relation of nephritis and renal sclerosis to diffuse hyperplastic sclerosis is sufficient to establish the intimate relation of the two conditions. It emphasizes the paramount importance of vascular lesions in renal disease, and it is this association that will, I think, ultimately lead to the solution of the causation of arterio-sclerosis. It is possible to assume, as have Aschoff, Gaskell, and others, that the vascular lesion is the cause of the renal lesion in my second group of renal sclerosis—the arterio-sclerotic group—a point of view that involves Gull and Sutton's conception of diffuse hyperplastic sclerosis as an independent disease of the vascular system. I hesitate to accept this view, because it cannot hold good for the relation of diffuse hyperplastic sclerosis to chronic nephritis and chronic interstitial nephritis. It is possible that the inflammatory changes in the latter are due to secondary infection, as has been suggested by Vollhard and Fahr,<sup>16</sup> a suggestion which is as difficult to prove as it is to refute. There is less objection to the view that the vascular disease is primary and the renal lesion a secondary atrophy in the hyperpietic and senile forms of arterio-sclerotic kidneys—Subgroup (b). At the same time this gives the

vasculature an identity of its own, whereas it is better regarded as merely part of the cardio-vasculo-renal system.

The basic proposition that I have attempted to present in this outline of the relation of hyperpiesia and renal sclerosis to diffuse hyperplastic sclerosis is that the causation of the vascular lesion is the same as the causation of hyperpiesia and renal sclerosis. The etiology of this condition, so far as it is known at present, is due to the action of bacterial toxins, and both the character of the vascular lesion in diffuse hyperplastic sclerosis and the distribution of the lesion in the vascular tree is compatible with the view that it is caused by a circulating toxin. Thus, with regard to the former, the character of the lesion is inflammatory; and with regard to the latter, it is known clinically from the distribution of amyloid disease and experimentally from the work of Welch and Flexner<sup>16</sup> and others, that a circulating bacterial toxin can readily cause both an unequal and a focal lesion of arterial walls.

#### THE RELATION OF OTHER FORMS OF ARTERIO-SCLEROSIS TO DIFFUSE HYPERPLASTIC SCLEROSIS.

##### 1. Nodular Sclerosis.

This lesion is like diffuse hyperplastic sclerosis in that the initial change is in the intima and in that the early stages show an intimal thickening due to proliferation of superficial cells, which Klotz<sup>17</sup> regards as either of endothelial or connective tissue origin. The intimal thickening is permeated by elastic fibrils at a later stage, and fatty degeneration occurs subsequently, perhaps as a result of deprivation of oxygen. Klotz and Manning<sup>18</sup> have made a minute study of the fatty streaks and spots that are chiefly found in the aorta and in the main vessels arising from it. They are of the opinion that these lesions may develop into nodular sclerosis and atheroma, an opinion shared by Jores and others; they say of these lesions that

"there is every indication that the production of tissue in the intima is the result of a direct irritation of that tissue by the presence of infection or toxins or of the stimulation by the products of a primary degeneration in that layer."

There is considerable evidence in favour of the view that these lesions, as well as those which are doubtless nodular sclerosis, are due to the effect of bacterial toxins. Klotz suggests that they are of an inflammatory nature, and he controverts Thoma's theory that the intimal thickening is compensatory to medial degeneration. From the information at present available it would seem that nodular sclerosis, in the nature of its lesion and in the site of its earliest appearance in the vessel wall, resembles diffuse hyperplastic sclerosis, while in other circumstances Thoma's theory may hold good—that it is a compensatory thickening secondary to an initial weakening of the media.

##### 2. Senile Arterio-sclerosis.

This form of arterio-sclerosis is primarily a medial degeneration, beginning with fatty degeneration and atrophy of the muscle fibres, and affecting the larger and smaller vessels.<sup>19</sup> Secondary to these changes occur replacement fibrosis and deposit of lime salts in the media. It is commonly accompanied by thickening of the intima, and nodular arterio-sclerosis is generally present in some degree. It differs from diffuse hyperplastic sclerosis in its clinical expression; age is more definitely a factor in its causation, and it is not accompanied by the cardiac hypertrophy and raised blood pressure of diffuse hyperplastic sclerosis.

Senile arterio-sclerosis is as diffuse in its distribution as diffuse hyperplastic sclerosis, but it differs from it both in respect of the site of the earliest lesion and in the character of this lesion. It is possible, therefore, that its causation is different; vascular lesions that have been produced experimentally, such as those caused by repeated adrenalin injections,<sup>20</sup> also by experiments (Klotz) in which arterio-sclerosis of the aorta was produced in rabbits by suspending them by their hind legs for two or three minutes daily for many days in succession, are of the nature of medial degeneration with calcification. Again, clinical conditions, such as mitral stenosis, that lead to an increased pressure in the pulmonary circulation sometimes (though not always) lead to arterio-sclerosis of the pulmonary artery in which degenerative changes are the prominent feature.

There is both clinical and experimental evidence, therefore, that mechanical and toxic causes may be responsible for that mechanical and toxic opinion on the mechanical causation of arterio-sclerosis expresses as well as any other

the generally accepted view. After reviewing the conditions in which an increased blood pressure is generally regarded as responsible for the vascular lesion, he remarks that "the factor of increased content of metabolites in the blood is also involved," and he expresses the opinion that an increased blood pressure cannot be excluded from the etiology of arterio-sclerosis, and that "it is without doubt an accessory factor in the production of arterio-sclerosis provoked by other causes." For a full discussion of this subject reference should be made to Allbutt, Andrewes, Thorel, MacCallum, and Moschcowitz.

Whether, however, a degenerative or proliferative lesion results from the action of a toxin on the vessel wall, may depend on the one hand on the nature of the pathogenic agent. On the other hand, the power of resistance of vascular tissues to the pathogenic agent must be an important determining factor, and it is possible that whether diffuse hyperplastic sclerosis or senile arterio-sclerosis result depends rather on the vitality of the tissues affected than on the nature of the pathogenic agent. There is some evidence in favour of this view, and factors such as age and inheritance find their due place in the tangle of causation in the extent to which they undermine and modify the reaction of vascular tissues to insult. Thus there is no reason to believe that age in itself is the cause of arterio-sclerosis, and Ophüls<sup>22</sup> has shown that the curve of incidence of arterio-sclerosis does not correspond with what would be expected if the lesion were the direct result of it and of the senile deterioration associated with it.

### 3. Mönckeberg's Sclerosis.

Mönckeberg's sclerosis illustrates this aspect of the problem from another point of view. The form of sclerosis that he describes is often included in the senile form of arterio-sclerosis; it does indeed often occur in old age, and it is like senile arterio-sclerosis in the fact that it is apparently a primary affection of the media and is characterized by calcification. In a sense it is more senile than senile arterio-sclerosis, for the intima often fails to proliferate, and when it occurs it is often late in the evolution of the lesion as a tardy process of repair. But it is not age that has weakened the vessel walls and prevented their reaction to insult—it is disease, not local but general; thus of the 12 pure cases described in Mönckeberg's original paper,<sup>23</sup> 4 died of cancer, 4 died of phthisis, 1 of advanced morbus cordis, and 3 of cachexia due to chronic infection. I think it is here that diabetes mellitus sometimes finds its place in the etiology of arterio-sclerosis.

### SUMMARY.

The study of the pathology of arterio-sclerosis has impressed me with the vivid picture of reaction in tissues to insult, response to injury, and repair of damage done. Great students of pathology such as Virchow interpreted the lesion in terms of inflammation, Thoma in terms of involution, and Jores in terms of growth. These men, at least, have failed to grasp the cloven hoof of decadence and decay. It is asking too much to expect a *restitutio ad integrum* in arterio-sclerosis, and, as in tuberculosis of the lung, we may well be content with a lesion that heals by calcification and fibrosis. The prospect of recovery in vascular tissue is indeed better than it is in the parenchyma of the lung; new vessels are formed more easily than new parenchyma. Louis Gross<sup>24</sup> has demonstrated the formation of new vessels in the kidney of renal sclerosis, and the rapidity of their formation is strikingly illustrated in thrombo-angitis obliterans, where new vessels may be formed in the lumen of the affected artery before the original process of disease has subsided, so that the new vessels may themselves be affected by the original process of disease. Again, it is remarkable evidence of the healing power of vessels that aneurysm of the aorta is rarely due to arterio-sclerosis even when present in a severe degree. There is a big field for inquiry in clinical medicine where evidence of the healing of arterio-sclerosis may be collected, and yet before the gate into this field is opened the clinical diagnosis of arterio-sclerosis needs a closer approach.

As the problem of arterio-sclerosis is contained in its definition, I will end by stating the problem as I have tried to outline it:

Arterio-sclerosis is a lesion characterized by a pathological thickening of arterial coats, particularly of the intima; inflammatory reaction is of first importance; degenerative changes are an essential part of the picture; hyperplastic

and involutionary processes play a part; no unit factor is responsible for its causation. Its development in its extent and form depends on a balance between the action of toxic agents and the power of resistance of the vessel wall to their attack.

In conclusion, it is a real pleasure to acknowledge the help and advice that I have received from Sir Frederick Andrewes, and the constant assistance kindly given by Sir Bernard Spilsbury.

## ON ANKYLOSTOME INFESTATION:

### THE CHANGING PROBLEM.

BY

CLAYTON LANE, M.D., LIEUT.-COL. I.M.S.(RET.).

THE present time seems particularly opportune to call attention to certain aspects of the hookworm problem which threaten to cause a division of opinion and procedure among those whose common desire is its solution.

It is probably undisputed that the aggregate of ankylostome infestation is enormous, hundreds of millions of persons being infested, that the effects of comparatively light infestations are harmful, and that an active hookworm campaign is essential. Beyond this point opinion is imperfectly crystallized. There is, for example, a weighty body which holds that the problem of ankylostomiasis is so great that it must be attacked along lines admittedly unscientific and deliberately rule of thumb. Their case is a reasoned one and can be put, I think quite fairly, thus:

1. The microscope fails to detect with certainty light hookworm infestations; so that, relying upon it, the sanitarian, intent upon producing complete disinfection, will find nothing but disappointment.<sup>1</sup>
2. The light infestations, those with less than ten worms, missed by the microscope, do not, however, damage their host; so that the fact that the microscope misses such infestations is actually an advantage.<sup>2</sup>
3. Accordingly the right way to attack the hookworm problem in any locality where infestation is shown to be considerable is to treat all persons indiscriminately, without attempt at individual diagnosis, with two treatments of oil of chenopodium.<sup>3</sup>
4. In this way 93 to 97 per cent. of the worms will be removed and all infestation material to the host will be eliminated.<sup>1,3</sup>
5. At the same time the soil will cease to be seriously infected, and reinfection of man will remain at the point where the resulting human infection will be immaterial.<sup>3</sup>
6. So that, in view of the inadequacy of microscopic diagnosis, and the practical adequacy of treatment, it is the duty of the sanitarian, faced with this huge problem, to concentrate upon the heavy cases which matter and disregard the light ones which do not.

### Microscopic Detection of Ova.

Whether infestation be light or heavy, the microscopic detection of ova in the stool is manifestly impossible if the worms be not ovipositing—that is to say, if only males be present, or if the females be too young, too old, or too ill to lay. If ova be present in the stool can they infallibly be detected there by the microscope, or is it the case, as stated in the fifth annual report of the Rockefeller Foundation, International Health Board, that microscopic technique fails to detect 50 per cent. of light infestations? The answer to this lies in some sixteen months' work of mine, financed first by the International Health Board and later by the Royal Society.<sup>4</sup> This work starts from the admitted position that hookworm eggs may be so sparse in a stool that the West Indian technique is fully justified. This requires that before a negative diagnosis is made nine faecal smears on 3 × 2 in.

slides, three simple and six from the deposit after centrifuging, should be examined. To save the enormous expenditure of time involved, a number of concentrative methods have been produced, designed to separate ova from faeces proper and to concentrate the former on a small area for microscopic examination. Since this work has involved the counting of over a quarter of a million hookworm eggs it rests on a foundation more solid than hitherto attempted. Since it has involved the eviction of the writer's own levitation technique from the premier position which he believed it to hold, the conclusions may reasonably be accepted as unbiased. Briefly the procedure has been as follows:

#### The Standardizing Count.

A measured quantity of stool is, by prolonged shaking with a comminutor, disintegrated into its constituent parts; it is clear that so long as faeces remain adherent to ova the ova cannot be collected apart from faeces proper. With a pipette this even faecal suspension is allocated into as many centrifuge tubes as there were cubic centimetres of original faeces. These tubes are now centrifuged for such time and at such rates as will, for the centrifuge in use, throw down all the suspended ova. In a centrifuge in which the bottom of the tube is 6½ inches from the centre this will be accomplished in sixty seconds at 1,000 revolutions a minute. The supernatant fluid is decanted. The deposit in each tube, all containing on the average the same number of eggs, is treated by a different concentrative technique and the ova recovered are counted. One tube is retained as a control, in order that a count may be made of the number of eggs with which each technique started. But since to make this count in smears in the centrifugal deposit from 1 c.cm. of stool spread sufficiently thinly would occupy several hours, the eggs in a measured fraction only of the control are counted, with due precautions for the maintenance of an even suspension, and for its accurate subdivision. This number, multiplied by the fraction, gives the average ovum content per cubic centimetre.

This controlling count I have named the "standardizing count." Subjected for the first time to this rigid mathematical control, it is evident that each technique has what may be termed its "limit of effective concentration," which is to say that it will, without appreciable loss, concentrate upon a certain examination area the ova from a certain quantity of a given stool, but that if, other things being unchanged, the quantity of stool be increased or the examination area be diminished, there occurs a loss of ova, at first relative and then absolute. Methods giving on occasions brilliant results have in the past been summarily rejected because on others they have miserably failed. That failure has been due almost solely, as I believe the internal evidence demonstrates, to their having been put to do that which was quite beyond their capacity, there having been no realization—as indeed there could not be without standardization—that the limit of effective concentration was the rigidly controlling factor which these counts show it to be.

The limit of effective concentration for levitation is, at the utmost, 0.5 c.cm. of stool upon 2 sq. in. of slide, and takes from twenty to thirty minutes for complete examination. In the Kofoid and Barber and in the Willis gravity flotation methods, modified in accordance with the ascertained limit of effective concentration, it is 1 c.cm. of stool upon 1 to 2 sq. in. of slide, taking ten to twenty minutes for complete examination. In the new centrifugal flotation method it is 1 c.cm. of stool upon a sixth of a square inch of slide, taking about two minutes for complete examination, while the control counts show that the number of ova lost during concentration by this technique is negligible. Moreover, the process of concentration is so simple that the ordinary unlettered coolie would have no difficulty in carrying out the whole of it. It seems, then, to fulfil the essentials for mass diagnosis and to combine rapidity, certainty, foolproofness, and cheapness to a degree not hitherto approached by any other technique.

This being so, does the 1 c.cm. of stool, which this technique uses, suffice for the detection of light infections? Baermann's work<sup>2</sup> indicates that each ankylostome female lays daily at least 1,000 eggs, or 10 ova per c.cm. in a stool of 100 grams. Darling's corresponding figures<sup>3</sup> for each female are an average of 2,237 ova daily, with maximum and minimum figures of 7,454 and 427.

The evidence, then, is that the properly conducted examination of 1 c.cm. of stool by direct centrifugal flotation will certainly, rapidly, and cheaply detect infestations by a single, normally ovipositing, female ankylostome. In other words, the microscope, properly used, can be relied upon to detect the lightest infections, and the statement that it misses 50 per cent. of light infections is incorrect.

There remains, under the second heading, the question whether infections with less than ten worms do not damage

their host. Evidence on this point is apparently lacking. It seems to be felt as inconceivable that a single pair of ankylostomes should harm their host, and this feeling is expressed, quite unjustifiably, as a direct negation. The position assumed is unsatisfying. It is that the microscope cannot detect less than ten hookworms, and that by an extraordinary coincidence it is just that number which matters. As has been pointed out,<sup>4</sup> a similar attitude has been adopted, quite incorrectly, regarding the centrifuge, and those who now make this statement must surely feel under an obligation to substantiate or reject it.

It is at least certain that there is a growing mass of evidence that the so-called carrier is improved in health and working power by disinfestation, and I know of no published evidence suggesting that there is any limit below which infestation is immaterial. Statements of personal belief on this matter appear misplaced. The fact seems to be that there is no satisfactory evidence either for or against the belief that the lightest infestations are immaterial to their host. With the definiteness in diagnosis which these new methods imply a few months' accurate examination in the field should suffice to settle this point and bring certainty where divergence of opinion is now expressed.

Are we justified in treating cases indiscriminately without diagnosis? In treatment we aim at employing poisons of such a nature and in such a manner that we poison all hookworms without poisoning the host. We are only exceptionally successful in accomplishing the former, and do not always succeed in avoiding the latter. Every established line of treatment has deaths to its discredit, so that every medical administrator who authorizes the administration of a potentially poisonous drug to individuals without any knowledge as to whether individually they are or are not infested must satisfy his own conscience on the matter. But if he satisfy himself that it is ethically permissible there remains the question, Is it politic for the campaign in question? Should a death occur after anthelmintic treatment as, with ankylostome treatment going on upon the scale necessary, must happen whether the drug had or had not any hand in its causation, unquestionably certain persons will say, "You have poisoned this man, and you did not even know that he was infected."

There are yet other moral questions involved. Just as every hookworm campaign uses and benefits from advances in scientific knowledge gained by previous ones, so is there surely an obligation, for the benefit of others, to add to that common stock of knowledge. It seems almost impossible to do so if diagnosis is to be dispensed with and treatment is to be merely by rule of thumb.

Regarding oil of chenopodium, it is true that in certain instances certain specimens have in two treatments removed 93 to 97 per cent. of the number of worms which three treatments evacuated. There is no evidence, and indeed with the methods of diagnosis hitherto employed there could be no evidence, that 93 to 97 per cent. of all the ankylostomes originally harboured were thus removed. With knowledge of the futility of these methods it is, indeed, gravely illogical to make this assumption. Moreover, oil of chenopodium is no fixed chemical compound and has no pharmaceutical standard. The work of Caius and Mhaskar<sup>5</sup> shows that its chemical composition varies, while as regards its anthelmintic value it must not be overlooked that in the Rockefeller Foundation's Panama campaign the drug was rejected as useless. It is, then, as premature to state that two treatments with oil of chenopodium will evacuate 93 to 97 per cent. of all worms as that these treatments will remove all infestation which matters to the host.

#### Ankylostomiasis a Privy Infection.

The present conception of ankylostome infestation is that the larvae are widely disseminated in the soil; and that those who work barefooted on the soil, especially agriculturists, are particularly liable to it. Ankylostomiasis has, indeed, been definitely and unhesitatingly designated as an occupational disease. But let us consider the latest evidence. According to the experiments of Augustine<sup>6</sup> there is practically no lateral migration of larvae in the soil. A circle four inches in radius round an infected spot marks, it is said, the extreme limits of larval excursion. Unless these experiments be disproved ankylostomiasis must be accepted as a stringently localized ground infection, something which I would designate as a *privy infection*, using the term "privy" to include (1) as a *privy infection*, using the term "privy" term a "natural man-made latrine; (2) what Cort and Payne<sup>7</sup> term a "natural

latrine," a selected and probably sequestered spot to which an individual will constantly return; (3) what may be designated a "casual privy," any spot whose use the call of the moment necessitates. Accepting these experiments it is impossible to admit that hookworm infection is a general infection of the soil, one which tends to evenness of diffusion; nor can one admit that it is of such a nature that the agriculturist must necessarily meet wandering larvae in the course of his work. Were this so, however, we could agree with those who clearly look upon the soil as one uniform whole more or less uniformly infected, and maintain that the amount of soil infection generally, and the consequent risk to those who work on it, must be proportionate to the number of ova which fall upon it—that is, to the number of ankylostomes harboured by the inhabitants. On such grounds, too, one would have to agree with Darling<sup>3</sup> that, could one reduce the number of ankylostomes to a certain level, one would reduce the larvae they breed to a point where human infection would be slight, and, if one be willing to concede this without proof, negligible; and that no increase in the infection rate of a community could occur without importation of a heavier infection from outside.

But, on the contrary, the evidence of Augustine's experiments is that infection must be constantly, presumably preponderantly, a "privy" infection, and that in the case of man-made latrines and "natural latrines" it is what I have termed a defectional infection<sup>10</sup>—obtained, that is, at the time of defaecation. Only in case of his skin coming into contact with ground which has been used as a casual privy will an individual acquire what I have termed a casual infection<sup>10</sup>; and that will generally be but seldom.

If, then, one conclude—and it is difficult to escape doing so—that recent evidence points to hookworm infection as being under ordinary conditions practically always a privy infection, and preponderantly a defectional infection, one is confronted with this question: Does the man-made latrine, as recommended by the sanitarian, prevent infection; or does it actively disseminate it? There will scarcely be opposition to the statement that ankylostome infestation cannot occur from a clean sewered water-closet, whence the infected stool is at once removed. But in those widely used, because widely recommended, latrines where the stools are dealt with *in situ* with a view to larval destruction, the position is unsatisfactory and disquieting. McVail<sup>11</sup> has found that ova and larvae, identified as those of hookworms, are constantly present in the effluent of those fine septic tanks which stand on the banks of the Hugli; Minett<sup>12</sup> and Khalil<sup>13</sup> have found them similarly in the West Indies; Khalil<sup>14</sup> quotes experiments to show that these larvae can swim; Payne<sup>15</sup> has shown that even if larvae do not migrate laterally on the surface of the ground, they can mount vertically through at least 36 inches of soil. Accordingly any latrine which permits of direct or indirect pollution of the soil or subsoil is, under present conditions, unsafe.

Since, apart from sewered latrines, there are such grave reasons for suspecting all man-made latrines as disseminators of hookworm infection, it is pertinent to inquire the extent to which a man, conscientiously using his privy and harbouring but a single pair of ankylostomes, will infect that privy. The answer lies in the work of Baermann and of Darling, to which reference has been made above. Assuming for the sake of even numbers that this particular pair of worms produced 2,740 fertile eggs daily, the number deposited in the latrine will be a million a year. We are assured that nine ankylostomes, or four to five million eggs a year, are hygienically negligible. It is not unreasonable to ask of those who are maintaining that this prodigious figure is hygienically negligible that they should either prove it or cease to urge it as a working hypothesis. There is an unfortunate disposition to take sides on this matter, and as one who is credited with leading the opinion that all infection matters<sup>2</sup> I would suggest that it is immaterial what anyone's opinion is, except in so far as it acts as a spur to the collection of facts. What is required is fact, and pending the collection of further facts there seems ample justification for the refusal to accept as personally or hygienically negligible any infection however slight.

#### *The Needs of Hookworm Campaigns.*

Seeing, then, that, by the evidence, accurate microscopic diagnosis is a reality; that treatment does not produce effective disinfection; and that ankylostomiasis must, on our present evidence, be looked upon as, in the main, a privy

disease, and not a general soil disease; the case which has been stated, and as I believe fairly stated, above collapses.

The problem is really a somewhat pathetic one. In the face of an urgent situation hookworm campaigns have been pushed forward. Certainly something had to be done; but the results are in certain respects deplorable. Promises have been rashly made which have not been, and could not be, substantiated, because the premisses on which the argument for their validity rested were unsound.

The present position would seem to be fairly stated thus: Diagnosis, thanks largely to the recognition of the principle of the limit of effective concentration, has now been placed in such a position that it will cheaply, certainly, and rapidly detect hookworm infection, provided normal oviposition proceed. Treatment and prevention lag far behind. We need a drug which will disinfect certainly, preferably in one treatment. Why should we rest content to say, as is said, that certain and complete disinfection is impossible of attainment? The acceptance of defeat in the situation is unthinkable. We need a latrine, simple, cheap, profitable, foolproof, suitable for the poor hut dweller. We have no approach to it, nor are we likely to have so long as there is no active dissatisfaction with, no strenuous striving to better, what we have. We need properly financed research to solve these and like urgent and vital problems in ankylostomiasis. We need research in order to avoid the heavy waste of money which has occurred so strikingly in the past in hookworm campaigns; for most of the work which has been done will have to be done again. Money spent in adequate research will come back multiplied many fold, not only in the capacity for work and earning, but in that measure of health, happiness, and length of life which our national commitments make it incumbent that we should at least offer to those backward races for whom we have made ourselves responsible.

## THE INFLUENCE OF INTESTINAL BACTERIA UPON THE THYROID GLAND.

BY

D. J. HARRIES, M.D., D.Sc., B.S., F.R.C.S.,  
SURGEON, CITY LODGE HOSPITAL, CARDIFF; ASSISTANT SURGEON,  
KING EDWARD VII HOSPITAL, CARDIFF.

SEVERAL years ago Sir Arbuthnot Lane suggested that exophthalmic goitre was produced by the toxins absorbed from the alimentary canal in intestinal stasis, and advocated colectomy as one of the methods of treatment. As a result of several years of study of the diseases of the thyroid gland I have arrived at the conclusion that his suggestion regarding the etiology of the disease was nearer the truth than most people thought at the time. His suggested method of treating the disease has not been widely adopted.

To appreciate the conclusions I have arrived at it is necessary to consider some factors arising out of the metabolism of certain proteins; these factors bear an intimate relation to the causation of diseases of the thyroid gland.

### *The Normal Digestion of Proteins in the Alimentary Canal.*

All proteins are broken down into amino-acids, and, with the exception of gelatin and some protamines, produce aromatic as well as other amino-acids. In this article I am concerned only with the amino-acid tryptophane. Normally a certain percentage of this substance is absorbed into the blood and utilized in the metabolism of the body; the remainder is decomposed in the alimentary canal, with the production of indole and skatole. These bodies are absorbed and then converted into indoxyl and skatoxyl potassium sulphates and excreted as such by the kidneys into the urine, where they can be identified and estimated.

### *The Importance of Tryptophane in Diseases of the Thyroid Gland.*

It has recently been shown by Professor Kendall that thyroxin, the active principle of the thyroid gland, is a tri-iodo tri-hydro derivative of tryptophane; the exact chemical formula is a matter of very little importance, as far as this article is concerned. For the time being I am taking for granted the generally accepted idea that exophthalmic goitre is due to the excessive production of thyroxin; that diffuse parenchymatous goitre is an attempt at producing a sufficient amount of thyroxin for the needs of the body by compensatory hypertrophy of the gland; and that in myxoedema there is a failure of the gland to produce the necessary amount of thyroxin. Acting on the assumption that these ideas were somewhere near the truth, I investigated the factors controlling the supply of tryptophane to the thyroid gland, and the variations in the supply in the diseases mentioned above. Theoretically we should find that in exophthalmic goitre the gland is well supplied with tryptophane, that in parenchymatous goitre the supply is inadequate, and that in myxoedema either the supply is very inadequate or else the gland is unable to utilize the supply available. Before proceeding farther it is necessary to have a rough idea of the normal flora of the intestine.

### *The Normal Flora of the Intestine.*

The flora can be divided into two main groups: the fermentative or acid producers, and the putrefactive or indole producers. Normally both groups are represented in the human intestine, but in disease, and experimentally in health, one group assumes undue, and sometimes absolute, predominance over the other. It has been proved that in the lower animals it is possible to change the predominant group in two to three days by making certain alterations in the food taken. In the human being, unfortunately, this is not easily done. Some time ago Dr. Distaso and I carried out a number of experiments on guinea-pigs, and found that the predominance of the indole producers runs parallel with the amount of indoxyl sulphate in the urine. We also found that by the addition of lactose to the diet we could destroy all the putrefactive indole producers in two to three days, and that the disappearance of the indoxyl sulphate from the urine occurred on the same day as the disappearance of the indole producers from the faeces. Within two days of discontinuing the lactose putrefactive organisms reappeared in the faeces and indoxyl sulphate in the urine.

### *The Application of these Observations to Diseases of the Thyroid Gland.*

During the last two years I have been fortunate in having a number of thyroid cases under my care at the City Lodge and King Edward VII Hospitals. The general practitioners of the district have also allowed me to examine several of their private cases.

Normally, in the human subject, the urine contains roughly 0.2 to 0.3 gram of organic sulphates and about 2 grams of inorganic sulphates per litre. The indoxyl sulphate was estimated by converting it into indigo and comparing the depth of the colour with a series of solutions of known strength. The total sulphates and inorganic sulphates were estimated separately by the benzidine method. I examined the urine of all the cases that I saw during the last two years, and I found that, as a rule, the total amount of organic sulphates runs parallel with the amount of indican in the urine. I also found that in all cases of well established exophthalmic goitre there was no indican in the urine. I now consider that the examination of the urine for indican provides a sound guide to the prognosis, as its early disappearance means that the case is certain to get worse. In

some very early cases I have been able to give such a prognosis.

If, in spite of medical treatment for two or three months, a particular case is not showing signs of improvement, and the symptoms are sufficiently pronounced to interfere seriously with the patient's health, I remove about half the gland—but only if there is no indican in the urine. The operation has no effect on the intestinal flora, or on the amount of indican in the urine, but the symptoms will be reduced for a few months, and during that period there may be a change in the flora. If there is no reappearance of the indole producers, then the symptoms recur, their severity depending on the activity and the amount of thyroid left. From these observations I concluded that the putrefactive indole producers had been exterminated in all cases of exophthalmic goitre, and that all the tryptophane was absorbed as such, and was therefore available for the production of thyroxin. The change in the flora takes place before the onset of definite exophthalmic symptoms and is responsible for the diminution, and later the disappearance, of the indican from the urine.

In cases of parenchymatous goitre there was no diminution in the amount of indican—in fact, most cases showed a slight increase with 0.4 to 0.5 gram of total organic sulphates per litre, indicating a predominance of the putrefactive indole producers. In these cases a fall in the amount of indican to below the normal is a sign of grave significance; it means that exophthalmic symptoms are likely to supervene—in other words, the indole producers are being replaced by the fermenters.

In one case of myxoedema investigated there was no indican in the urine—a condition suitable for the development of exophthalmic goitre—and the absence of symptoms can be explained by the atrophic condition of the gland found in all cases of myxoedema.

### *The Intestinal Flora in Exophthalmic and Parenchymatous Goitre.*

Dr. W. Parry Morgan has kindly examined the faeces of some of my cases, and his results have been exactly what I expected from my analysis of the urine and the results obtained experimentally in lower animals by Dr. Distaso and myself. In other words, the indole producers are absent in exophthalmic and present in parenchymatous goitre.

It is well known that women often develop parenchymatous goitre in the hill stations of India, and McCarrison has shown that this is due to the contamination of the drinking water by a coliform type of bacillus, an indole producer, which is what one would expect. It is possible that the altitude has something to do with the rapidity with which the indole producers obtain predominance, as it has a definite influence on the rate of growth of various bacteria.

### *Methods of Altering the Character of the Intestinal Flora.*

Distaso showed that, in rats and guinea-pigs, the addition of lactose to the diet for two or three days suppresses the growth of the putrefactive group. Torrey showed that dogs behaved in much the same way, and that dextrin acts more powerfully than lactose; also that unboiled milk and animal proteins stimulate the growth of putrefactive organisms, while boiled milk and vegetable proteins tend to suppress them. Distaso found that, in the healthy human being, lactose, given by the mouth, produces very little effect on the indole producers, and this explains the absence of any change in the amount of indican found in the urine.

### *TREATMENT OF EXOPHTHALMIC AND PARENCHYMATOUS GOITRE.*

It is unnecessary to discuss the treatment of myxoedema as this is now familiar. The fact that the administration of thyroid extract has to be continued as long as the patient lives shows that the thyroid gland never recovers once myxoedema is established, and the absence of indole producers from the intestine shows that the disease is not caused by an undue destruction of tryptophane, but by the inability of the thyroid to utilize the material at its disposal. In parenchymatous goitre it is necessary to encourage the growth of the fermentative group by cutting down animal proteins and giving fats, vegetable proteins, boiled milk, rice, bread, and dextrin or lactose. The amount of lactose required to produce any appreciable effect is considerable—1/4 to 1/2 lb. a day—and therefore not within the realm of practical treatment.

In exophthalmic goitre unboiled milk, eggs, and fish should be given freely. The supply of meat protein should be controlled by the symptoms and the examination of the urine. In the complete absence of indican, and therefore of putrefactive organisms, the administration of meat aggravates the symptoms, but in the presence of indican meat will encourage the growth of the putrefactive bacteria already present. I have found that in the complete absence of indican the patient is more comfortable if all animal protein is withheld, and jelly given instead. The reason is obvious, as jelly contains no aromatic radical. In serious cases, with pulse rates of 150 or over, I have found this fact of great value. It is rare for the pulse rate not to fall below 120 if animal protein is withheld for a fortnight; in addition, the patient feels better, and the dangers of an anaesthetic will be reduced if the goitre has to be treated surgically.

#### Operative Treatment of Goitre.

Obviously, a case of parenchymatous goitre with no exophthalmic symptoms superadded is not benefited by removing a part of the gland unless the trachea is pressed on and the breathing interfered with. Ladies, however, are prepared to sacrifice a lot in the interests of their personal appearance. Needless to say, I am not referring to adenomatous or cystic goitres, which are obviously surgical conditions.

In exophthalmic goitre I am guided by the intensity of the symptoms, by the result of dietetic and medical treatment, and especially by the absence or presence of indican in the urine. The complete disappearance of indican, as I have already insisted, means that the chances of early improvement are remote, and if the symptoms are at all severe I advise operation. Partial thyroidectomy improves the patient for several months, as it diminishes the amount of thyroxin manufactured. The operation does not attack the cause of the disease, but the improvement in the symptoms may be enough to justify the operative risk. Both parenchymatous and exophthalmic goitre are diseases which run a definite course; the patients get progressively worse up to a certain point, and then, for no apparent reason, they improve, and ultimately get perfectly well—provided, of course, that the symptoms have not proved fatal before improvement sets in. The patients commence to improve when the intestinal flora becomes normal, and, in all probability, an acquired immunity to the suppressed organisms explains the difficulty found in re-establishing the normal flora in these cases. When the subject has been more fully investigated it may be possible, if such is really the case, to diminish or destroy this immunity. Possibly equally good results might be obtained by increasing the immunity of the body to the predominant group, as this would encourage the growth of the opposite group. It is possible that the improvement following removal of a part of the gland in exophthalmic goitre has a definite effect on the degree of immunity to the putrefactive group.

Unfortunately, bacteriology is still in a very primitive stage of development; comparatively unimportant matters have been fully investigated, such as the exact type of growth obtained on rare and complicated media, but very little interest seems to be taken in the exact chemical composition of the bodies formed by pathogenic bacteria when growing in animal tissues. When this subject is worked out, then we can hope to make a decided advance in our methods of treating the diseases caused by them.

The treatment of goitre by means of  $x$  rays is a non-operative method of destroying a part of the gland tissue, and its use should be regulated by the same considerations that govern operative treatment.

#### Medicinal Treatment of Goitre.

In parenchymatous goitre I doubt if any preparation does as much good as the local application of dilute mercuric iodide ointment; its beneficial results may be due to the excretion of some of the mercury into the alimentary canal. In exophthalmic goitre treatment is mainly symptomatic, and is useful in that it improves the patient's general condition and comfort; it does not cure the disease, and no one pretends that it does.

#### GENERAL CONCLUSIONS.

1. Exophthalmic goitre is due to the excessive absorption of tryptophane from the intestine; this in turn is traceable to the absence of the indole producers from the intestine.
2. The absence of indican from the urine indicates the absence of indole producers from the intestine.

3. In exophthalmic goitre the early disappearance of indican from the urine is of serious prognostic importance.

4. Operative surgery has a definite place in the treatment of exophthalmic goitre. Medically, much can be done by suitable dietetic measures.

5. Diffuse parenchymatous goitre is characterized by an excess of indican in the urine, suggesting an excessive destruction of tryptophane. If this excess gives place to a diminution or complete disappearance of indican, that suggests that the case is assuming the exophthalmic form.

6. Myxoedema is due to atrophic changes in the thyroid gland, which loses its capacity for dealing with the circulating tryptophane, whether that substance be excessive, deficient, or normal in amount. The disease is thus compatible with the presence or absence of urinary indican.

## THE TREATMENT OF INCIPIENT PHTHISIS.

BY

WILLIAM GORDON, M.D., F.R.C.P.,

SENIOR PHYSICIAN, ROYAL DEVON AND EXETER HOSPITAL.

More than a quarter of a century has now elapsed since the open-air treatment of phthisis was brought home again to this country by Dr. Burton-Fanning of Norwich and Dr. Jane Walker, and the time is ripe for a general stocktaking of sanatorium experience.

#### ENGLISH SANATORIUMS.

There is a general impression that this experience is on the whole disappointing, and recently Dr. Ernest Ward has shown that in his district working-class cases of phthisis have done better in their own homes than those sent to a sanatorium.

No one who remembers working-class consumption thirty years ago will regard open-air treatment as anything but a great advance; and since it was in sanatoriums that open-air methods were developed, no one can hold that sanatorium treatment in a general sense has failed. If there is failure in England, it must be due either to our climate or to defects in individual sanatoriums. That England is less capable than other countries of furnishing the best results is unproved, though the point needs investigation. But that individual sanatoriums are unsatisfactory is suggested by the variations which are becoming evident in the results of treatment in different localities.

#### THEIR HISTORY.

*Bodington.*—The open-air treatment of phthisis was an English discovery, first announced, in 1840, by Dr. George Bodington of Sutton Coldfield, but the English medical profession turned it down.

*Görbersdorf.*—Happily for the tuberculous, the German realized its value. In 1859 Brehmer opened the first open-air phthisis sanatorium at Görbersdorf in Silesia, and I would draw attention to two points about this sanatorium which have been curiously overlooked. In the first place Brehmer chose a locality almost free from indigenous phthisis. In the second place he chose a site which was exceptionally wind-sheltered.

*Davos.*—In 1862 Spengler of Davos pointed out that indigenous phthisis was rare amongst the inhabitants of his valley, and that such of them as had contracted it elsewhere frequently recovered on returning to their homes. In 1855 patients from Germany began to be sent to Davos and the results were eminently satisfactory. In Davos also there is remarkable wind-shelter, and this "wind-stille" has been insisted on by all competent writers as an important factor in the curative influence of the place.

*Nordrach and Falkenstein.*—The success of Görbersdorf led to the establishment of daughter sanatoriums in different parts of Germany. Two of these have been specially noteworthy—namely, Dettweiler's at Falkenstein and Wallther's at Nordrach. Nothing could be more striking than the contrast between their sites and their fortunes. For the first time in the history of sanatoriums we come upon a disappointment. Nordrach was a success; Falkenstein has been demolished.\* Falkenstein, the failure, stood high on the southern slopes of the Taunus, "well protected from north

\* The reason of the closure of Falkenstein has of course to be inferred. Medically successful phthisis sanatoriums do not close down. It is noteworthy that a new sanatorium has arisen at Falkenstein and that the sanatorium for the poor, opened at Falkenstein by Dettweiler on a small scale in 1892, was afterwards moved to a very different site, in marked shelter from westerly winds, at Rupperts-lahn, where it remains.

and east" (in the phrase so dear to some medical writers), but imperfectly protected from the western gales. The phthisis death rate of the neighbourhood was 4 per 1,000. Nordrach, the success, is situated in the heart of the Black Forest, at the end of a very sheltered valley, enclosed on all sides by forest-covered heights, facing south-east and with abundant sunlight, under a heavy rainfall, but on a porous, quickly drying sandstone soil, too high to be reached by the far-travelling Rhine fogs, remote from the dust of traffic and from the possible infections of neighbouring communities, and provided with numerous sheltered walks in the surrounding forest. So striking was its success that it became the Mecca of English chest specialists.

Walther.—This brings us to a very interesting personality—very fateful, as I believe, in the history of English sanatoriums—Dr. Otto Walther, "devoted to the English." We English owe mainly to him, I have little doubt, the highly interesting field of climatological inquiry afforded by the surprisingly variegated choice of sanatorium sites made in this country. For to me he gave precisely the advice that I was tired of hearing at home, having by that time discovered how incorrect it was. I visited his valley soon after 1900, and was at once impressed by the skill displayed in his own choice of locality. Walther had by no means followed the almost happy-go-lucky advice he gave to me; and Sir James Fowler has just told us that "it is clear that Otto Walther did not consider the site of his own sanatorium as of little or no importance. He visited more than 200 sites before finding one suitable!" Why, then, did he give his English visitors views so different from those indicated by his own most careful choice, without one word about shelter? One does not know. But his pilgrims went home, full of Teutonic inspiration, and sowed their sanatoriums broadcast, at immense expense, in the manner he had indicated, and have been wondering ever since why the success they looked for has hitherto eluded them!

#### THEIR DIFFERING RESULTS.

Only a few sanatoriums seem, so far, to have stated after-results. Dr. Ward's results in South Devon are so strikingly the best that, although his figures are smaller, it is necessary to include them. Seeing that the critical years, in which most deaths occur, include the first four years, we had better confine our attention to his results at the end of four years. For comparison we must deal with other statistics similarly, and this limits us to Frimley Sanatorium (1914 report), Midhurst Sanatorium (fourteenth annual report, 1920), and "Tuberculosis in London" (Dr. Bardswell, *Tubercle*, 1921). I shall only consider the mortalities. Also I shall only deal with "early cases."

Dr. Ward recognizes three stages of the disease—"slight, medium, and extensive." No distinction was drawn between cases showing tubercle bacilli and cases not showing them. For comparison, therefore, we must take together, in the other statistics, the tubercle-positive and tubercle-negative cases on admission. In the Frimley report I have considered the "full-time" cases. As equivalent to Dr. Ward's "slight cases" I have taken those described as "having physical signs indefinite or in one lobe." In Dr. Bardswell's paper the "early cases" are those of the Turban-Gerhardt classification. "Almost without exception, the patients underwent treatment in a sanatorium." The patients in these three categories are almost wholly "working-class."

The Midhurst report gives tables which make it possible for one to calculate the results of all the early cases at four years after their discharge; the Turban-Gerhardt classification is used. At Midhurst a much higher class of patient is dealt with.

Comparison of Results at Different Sanatoriums.

	No. of Cases.	Percentage Dead after Four Years.
South Devon (Dr. Ward)—		
Not been in sanatorium ... ..	114	2.6
Been in sanatorium ... ..	55	11.0
Frimley ... ..	197	15.0*
Midhurst ... ..	552	20.0†
"London cases" (Dr. Bardswell) ... ..	903	31.0

\* Not including 39 per cent. lost sight of.  
† Three per cent. lost sight of.

Here are surely differences which call for explanation. The reports are by able men; the sanatoriums, so far as they can be identified, are well built and arranged; the patients have been under most skilled care. Then why these differences? Have the sites anything to do with them? That site may exercise an influence the history just given suggests. My own work, published in 1900 and since, strongly suggests it.

The importance of site is gradually becoming recognized. A friend, interested in the matter, has told me a conversation with one who had worked in two Scottish sanatoriums—one on the rainy west, one on the drier east—who said that the patients in the east had done much better than those in the west. Again, at a meeting of the Tuberculosis Society last year the tuberculosis officer of an important northern district told us that formerly all their phthisis patients were sent to a neighbouring seaside town, which the map shows to be exposed to practically every wind, where, as he tersely put it, "they all died," and that, in view of such results, the new sanatorium was being built inland and in shelter from rain-bearing winds.

#### THE NECESSARY INQUIRY.

I would submit that an inquiry into the results of all sanatoriums in this country is necessary and might be carried out somewhat as follows:

1. Early cases only should at first be considered.
2. Only cases with bacilli in the sputum should be dealt with.
3. The results should be stated for each case at the end of five years, especially the "apparent cures" and the deaths.
4. "Working class" cases and well-to-do cases should be separated.
5. For the well-to-do the results should further be compared with those at foreign sanatoriums similarly treated.

#### INTERIM PROCEDURE.

In the meanwhile what are we to advise when an early case of phthisis comes before us? My own strong opinion is that he should be warned sedulously to avoid the following climatic conditions:

1. The tropics, except at certain great altitudes in wind-shelter, as in some valleys of the Andes.
2. The immediate sea front (a quarter of a mile inland seems to avoid its bad effect).
3. A damp soil.
4. Impure or dusty atmosphere.
5. Deficient air supply.
6. Deficient sunlight.
7. Fog.
8. Exposure to strong, prevalent winds, especially rain-bearing winds.

We obviously would keep at home cases of acute miliary tuberculosis; acute tuberculous bronchopneumonia; acute tuberculous lobar pneumonia in its acute initial stage; pulmonary tuberculosis supervening on any serious condition rendering home treatment desirable.

Those whom we may send away we shall do wisely first to send to a well placed and well managed sanatorium in this country. If the case seems to be doing well in the sanatorium, he would probably be well advised to stay for six months or longer. When he leaves, if he be a "working-class" patient, he will be fortunate if some open-air colony, in which he can work under supervision, is open to him, such as Dr. Burton-Fanning has instituted in connexion with the Kelling Sanatorium in Norfolk. If he is "well-to-do," the question arises whether England is the best place for him.

In England, I would advise some locality where phthisis is known to be uncommon and where climatic advantages, including shelter, seem to account for its rarity.

We must not lose sight of Dr. Theodore Williams's remarkable figures published in 1891. Dealing with "first stage" cases, "affecting one lung only," we may arrange them in tabular form, thus:

#### Percentages of "Arrest."

"High altitudes" (mainly Swiss) ... ..	63
Sea voyages ... ..	17
Riviera and South Europe ... ..	7

Of "high altitudes" he wrote: "The most surprising feature is the large figure of absolute arrests, which not only were far more numerous than in other climatic results, but were more complete."

I think it may fairly be said that early cases—young, vigorous, uncomplicated, with little or no fever, however

beginning (so long as haemoptysis has ceased)—will get their best chance at Davos, or at some other Alpine station with the climatic conditions of Davos—namely, pure, still, dry, cold, diaphanous, and diathermic air.

Unsuitable early cases for the high Alps are: acute cases, nervous, irritable people, elderly people, chilly people, most laryngeal cases, and those with much emphysema, with heart disease, or with albuminuria.

In choosing other foreign climates than Switzerland we must not forget that Australia, New Zealand, the Cape, Canada, and the United States no longer admit cases of active tuberculosis.

This leaves us a rather narrow choice. Sea voyages are by no means a safe prescription, particularly if they cross the tropics. The Riviera does not appear to give better results than can be obtained in England. Egypt at the present moment does not suggest itself as desirable. Las Palmas in Grand Canary has given good results; its climate should not be confused with the quite different climates of Orotava in Teneriffe and of Madeira. South-eastern Spain and the desert behind Algiers are still advised. In sending phthisical patients long distances their travelling powers must be considered, as well as the luxuries of travel and accommodation which they are prepared to allow themselves; also, and very important, the medical skill available in the health resort decided on. In the light of home sanatorium results all these localities will require consideration.

#### CONCLUSION.

To conclude, I would like to leave it clear that, from the foregoing comparison of open-air results, I claim to draw no final inference. They are too few, the definitions of "early" are too various, and the absence of uniform finding of tubercle bacilli renders the diagnoses too uncertain. *What I do claim, and claim strongly, is that they constitute a case for immediate investigation.*

## ACUTE PUERPERAL INVERSION OF THE UTERUS.

BY

C. S. LANE ROBERTS, M.S., F.R.C.S.,

CHIEF ASSISTANT AND TUTOR, WOMEN'S DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL; PATHOLOGIST AND REGISTRAR, SORO HOSPITAL FOR WOMEN.

The two cases of puerperal inversion here recorded were recently met with in hospital practice, and are published by Dr. Croft's permission.

#### CASE I.

A. L., aged 21, 2-para (the first being a miscarriage), a healthy woman with strong abdominal muscles, had a normal first and second stage, the latter lasting two hours; twenty-five minutes later the uterus was grasped to see if the placenta had separated, and as it was uncertain whether separation was complete control and pressure were maintained on a well contracted fundus, and, the patient of her own accord bearing down, part of the placenta appeared at the vulva. During this time there had been no excess of haemorrhage; the sister in charge then said the hand on the abdomen seemed to lose the uterus, and the emerging placenta was gradually followed by the completely inverted uterus, the whole appearing slightly larger than a foetal head, with part of the placenta separated but quite two-thirds remaining attached to the uterus, which accounted for the uncertainty of separation and the slight haemorrhage only. At once the parts were surrounded with hot sterile towels and the best available antishock treatment instituted.

Thirty minutes later (that is, fifty-five from delivery) I saw the case, finding the degree of shock markedly progressive, the patient looking extremely ill, with deep sighing respiration and almost imperceptible pulse. The inverted structures were not examined, but the abdomen gave no uterine swelling whatever, so that the condition was evidently one of complete uterine inversion. It was decided to leave the uterus *in situ*, with the placenta attached to avoid superimposing any haemorrhage on the prevailing shock. The antishock treatment was continued, though no morphine, no pituitrin, and no intravenous medication were administered, subcutaneous saline, hypodermic camphor, and ether being given.

Fifteen minutes later (that is, seventy from delivery) the patient appeared moribund, the pulse being quite imperceptible; so, as (1) her condition seemed hopeless, (2) she had not reacted to antishock treatment given for forty-five minutes, but had become steadily worse, (3) the husband had been sent for, (4) the apparatus was ready for an instant blood transfusion, it was decided to risk replacing the uterus. Accordingly the placenta was peeled off the uterus, very little haemorrhage occurring; the uterus was quite easily replaced through the relaxed cervix, and a hot intrauterine douche given; no pituitrin was administered as there was no bleeding of any account, and injec-

tion of this drug has been followed by reinversion. It was difficult to decide on the immediate effect of the replacement, as the general condition seemed so bad, but it appeared still further to deepen the shock, so that the case became quite hopeless.

Ten minutes later (that is, eighty from delivery) the husband arrived, so that transfusion was immediately performed of 22 ounces; the patient's colour slowly returned, and her condition improved.

The puerperium was apyrexial, and the lochia normal; on the fourteenth day vaginal examination showed the uterus a little bulky, but otherwise normal in shape, consistence, mobility, and position, so that the patient was discharged the same day.

#### CASE II.

A. H., aged 22, one previous child, had a difficult labour (forceps delivery) and severe post-partum haemorrhage. She got up on the tenth day and seemed quite well till the sixteenth day, when during the act of defaecation she felt her "womb drop"; the doctor sent for made a diagnosis of uterine inversion. The patient was admitted to hospital on the seventeenth day under Dr. Croft. Under an anaesthetic the vagina was found to contain a sloughy-looking mass, corresponding in shape and size to the inverted fundus of the uterus; the body of the uterus was not felt on bimanual examination. Manual replacement was found difficult owing to the rigidity of the cervix—the operation took close on forty minutes; it was followed by an intrauterine douche and iodoform pack; the chief difficulty, Dr. Croft said, was to start a dimpling of the uterine wall.

The puerperium was not eventful, and vaginal examination on the fourteenth day disclosed the body of the uterus normal and the cervix closed.

In the first case the result would certainly have been fatal had it not been possible to do blood transfusion. Owing to the lack of response to the antishock treatment, it seemed that there was nothing to be lost by risking replacement of the uterus, but the effect was apparently to deepen the shock as far as could be discerned with the patient in so precarious a way.

The ideal treatment would appear to be immediate blood transfusion with later replacement of the uterus. If blood is not available it would be worth while to try gum acacia solution, but saline seems useless if not harmful in certain cases.

Reference might be made to a case reported by Dr. Barris<sup>1</sup> of blood transfusion in a case of uterine inversion in which, two hours after delivery, the midwife tried forcibly to express the placenta and made traction on the cord, with the result that the patient felt something come down, and was admitted to hospital eleven hours later with the fundus inverted inside the vagina; the immediate treatment with pituitrin and a vaginal douche was directed to the prevention of shock. Two days later the first blood transfusion of 100 c.cm. was performed, and twenty-three days after that a second of 600 c.cm. Reposition of the uterus was done in the seventh week with an Aveling repositior, as there had been local sepsis and Carrel treatment had been called for.

The second case falls more into line with the series published in 1920 by Dr. Spencer, of which the first three cases were admitted with the inversion on the fifth, ninth, tenth, and twenty-second days, reduction taking place on the sixteenth, fortieth, and twenty-second days respectively, though in each it was uncertain when the actual inversion occurred; the next two cases occurred nine months, and two years and eight months, after labour; the last four being associated with tumours, and appearing seven, twelve, thirteen, and twenty-five years after labour, reduction in each case being effected by Aveling's repositior.

#### REFERENCE.

<sup>1</sup> Transactions of the Royal Society of Medicine, January, 1921.

DR. HUBBARD, director of public health education of the New York Department of Health, has recently published statistics which appear to show that since the last year before the prohibition law took effect there has been a constant increase in New York in the number of arrests for drunkenness, the number of deaths due to wood alcohol poisoning, and the number of persons admitted to hospital suffering from acute alcoholism. During last year 5,624 persons suffering from acute alcoholism were admitted to Bellevue and King's County hospitals, as compared with 3,545 in the preceding year. In 1922 the number of deaths from alcoholism was 295, as against 141 in 1921. The number of deaths, however, is smaller than it was in the years preceding prohibition; in 1916, for example, 690 persons died in New York from alcoholism; the low-water mark was reached in 1920, when there were 127 deaths, but since that time there has been a rapid increase. The number of arrests for drunkenness in New York in 1922 was 7,856, as against 6,233 in 1921.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

### PSORIASIS.

In the BRITISH MEDICAL JOURNAL of July 8th, 1922, appeared a note recording marked benefit to a case of psoriasis by the administration of collosol manganese.

Having several cases under my care, I gave the method a trial. The first was an obstinate case of six years' duration. After eight doses she appeared on the high road to recovery, and I felt that at last a cure was found for an old enemy. Bearing in mind the danger of drawing conclusions from insufficient data, and the fact that patches of psoriasis often exhibit a tendency to clear up with almost any standard treatment, I placed seven other patients under the treatment.

The drug used was Crookes's collosol manganese, which was given by intramuscular injection. Vaseline was applied locally to the patches. No other medicine, internal or external, was used. The patients were girls of ages 12 to 17 years. Dose: four injections of 0.5 c.cm. at four-day intervals, followed by doses of 1 c.cm. for five to eleven doses.

Brief notes of the cases follow:

Case 1.—D. C., aged 17. Distribution: Head, back, chest, axilla, arms, and legs. The patches varied from the size of a threepenny piece to larger than that of a five-shilling piece. After receiving four injections of 0.5 c.cm. and four of 1 c.cm. the patient was immensely better—had not been so well for six years; there were only scars and staining. Treatment was continued, and seven further doses of 1 c.cm. were given. The improvement was not maintained, and within four months patches recurred as at outset.

Case 2.—A. G., aged 16. Elbows and knees had patches varying from the size of a shilling to that of half a crown. Treated with four injections of 0.5 c.cm. and seven of 1 c.cm. No improvement.

Case 3.—D. S., aged 16. Elbows, knees, and legs chiefly affected, the size of the patches ranging from that of a shilling to a threepenny piece. Had four doses of 0.5 c.cm. and seven of 1 c.cm. No improvement.

Case 4.—L. V. G., aged 14. Small patches on elbows, knees, legs, and back. Had four doses of 0.5 c.cm. and six of 1 c.cm. No improvement.

Case 5.—M. P., aged 11. There were patches from the hip to the knee the size of half a crown; from knee to ankle, and on chest, back, arms, and scalp they varied in size from that of a threepenny piece to a sixpence. The patient was treated with four injections of 0.5 c.cm. and eleven of 1 c.cm. There was no improvement.

Case 6.—M. Mc., aged 15. The arms had patches varying in size from that of a threepenny to a five-shilling piece; smaller patches on thighs, legs, and buttock; the back and scalp were also affected. Received four doses of 0.5 c.cm. and six of 1 c.cm. No improvement.

Case 7.—H. H., aged 11. There were patches on the back the size of a shilling to a five-shilling piece; large patch on thigh, and several patches on chest. Had four injections of 0.5 c.cm. and ten of 1 c.cm. The back showed slight improvement; no improvement of thigh.

Case 8.—N. L., aged 12. A few patches. Had four injections of 0.5 c.cm. and five of 1 c.cm. Slight improvement.

G. GUSHUE-TAYLOR, M.B., B.S., F.R.C.S.

Barkingside.

### PREGNANCY IN A FIBROID UTERUS.

A NATIVE woman, aged 26 years, was admitted to hospital on October 24th, 1921, with symptoms which seemed to point to suppurating ovarian cyst, pyosalpinx, or ectopic gestation. There was a tumour on the left side of the pubes and a painful mass, which could be felt from the vagina, behind the cervix. She had a good deal of pain, which had increased very much since she had been previously discharged from hospital, on October 17th. She had been admitted originally for the same complaint on October 5th, 1921, and after rest in bed and fomentations the pain was relieved, but as I was not sure as to the presence of pregnancy I decided to wait, and discharged her from hospital. However, she was readmitted, and two days later I operated. I found that the uterus was a mass of fibroid tissue, except for the anterior surface; a fibroid tumour, about the size of an orange, projected from the postero-superior surface. The uterus was becoming impacted in the pelvis; it was removed by subtotal hysterectomy, and was found to contain two fetuses of about two months' development. The patient was unmarried and at first denied the possibility of pregnancy, but later admitted having missed one period. She was discharged from hospital quite well on November 28th.

## British Medical Association.

### CLINICAL AND SCIENTIFIC PROCEEDINGS.

#### BIRMINGHAM BRANCH.

THE third ordinary meeting of the Branch was held at the Medical Institute, Birmingham, on February 15th, the chair being taken by Mr. ALBERT LUCAS, President of the Branch. Mr. SEYMOUR BARLING opened a discussion on "The diagnosis and treatment of chronic ulcer of the body of the stomach."

Having referred to the many unsettled problems connected with the etiology of the initial condition and the causes which led to recurrence, Mr. Barling proceeded to a detailed assessment of the relative values of clinical, radiographic, and chemical investigations in arriving at a diagnosis. Two former must, he said, be considered: radiography gave a confidence and accuracy which nothing else did, it was occasionally wrong. With reference to treatment, the scope and limitation for medical treatment were first considered, and then the most suitable surgical procedures discussed. Mr. Barling considered that the ideal operation should consist in removal of the site of the ulcer together with a drainage operation, to alter the physiological and mechanical conditions of the stomach. These criteria were secured by partial gastrectomy, also by excision of the ulcer or its destruction by cautery, followed by gastro-enterostomy. He did a partial gastrectomy in more than half his cases at the present time, but preferred the less mutilating operation of excision and gastro-enterostomy in the less severe cases. In his experience malignant disease following ulcer was of less frequent occurrence than the figures given by many surgeons would have led one to suppose. In a series of fifty five cases, of which 50 per cent. were of ten years' standing or over, only two were found in which clinical or microscopical evidence pointed to this having occurred.

Mr. W. BILLINGTON advocated double gastro-jejunostomy, in order to drain the stomach on each side of the ulcer, together with entero-enterostomy. He pointed out that this operation was applicable to all cases, whereas partial gastrectomy was not. He found that this procedure gave immediate results greatly superior to any other method he had tried, and after four and a half years' experience of it had had no cases returned to him with recurrence of symptoms.

Dr. HAROLD BLACK said that as a rule no help was afforded by radiography in the detection of acute ulcers. In chronic ulcer positive evidence of the presence of ulcer was obtained when the actual ulcer crater was seen. When no crater was seen the presence of ulcer might be surmised when certain changes in the anatomy or function were present. These changes were demonstrated by lantern slides and their reliability as evidence discussed.

Dr. T. L. HARDY stated that fractional studies of the gastric contents in these cases showed that the curves mainly followed the normal type and that help in diagnosis could not be expected from them. As regards treatment, he thought that this should invariably be carried out in three stages—preliminary treatment, treatment proper, after-treatment. The work of Rosenow, and more recently that of Kopeloff, afforded ample experimental evidence of the importance of infection in the mouth, nose, and nasopharynx, and the removal of septic foci as a necessary and preliminary step. He pointed out the principles on which treatment proper should be based, due weight being given to x-ray and chemical findings. He laid special emphasis on the need for prolonged and thorough after-treatment, and thought that results would be greatly improved if more attention was paid to this aspect. The better education of the patient in regard to his disability was much to be desired, and written instructions as to diet and mode of life should always be given.

Dr. G. A. WILKES said that it was the part of the general practitioner to diagnose gastric ulcer in its early stages. He mentioned the three cardinal symptoms of pain, hæmatemesis, and melaena; but at an earlier stage he pinned his faith to the "nerve reflex" of skin and muscle tenderness with rigidity. Recurrent attacks of the nerve reflex meant ulcer. The position of the tender area indicated the position of the ulcer in the stomach.

Sir GILBERT BARLING emphasized the necessity of excising the gastric ulcer and of performing gastro-enterostomy at the

same time. He had adopted this as the operation of choice many years ago after a fatal case of haemorrhage following gastro-enterostomy. The haemorrhage had taken place from the floor of the ulcer, which had not been excised at the time of operation. Additional reasons for the excision of the ulcer were the risks of perforation and cancer. The latter followed simple ulcer sufficiently often to make excision imperative. Finally, the patient whose ulcer was left *in situ* led a very miserable existence.

#### CAPE OF GOOD HOPE (WESTERN) BRANCH.

##### *Infective Tonsillar Disease.*

A MEETING of the Cape of Good Hope (Western) Branch of the British Medical Association was held in Cape Town on February 23rd, when the President, Dr. C. M. MURRAY, occupied the chair. The business of the evening was a debate on "The etiology, symptomatology, and treatment of infective tonsillar disease," organized by Mr. C. E. JONES-PHILLIPSON.

Dr. W. P. MULLIGAN opened the discussion with an account of the bacteriology and etiology from the laboratory viewpoint. He divided infective tonsillar disease into acute and chronic types: the former included pyogenic infections, Vincent's angina, diphtheria, and scarlatina; the latter comprised tubercle, syphilis, and numerous obscure tropical conditions, which produced infective tonsillitis. Predisposing factors, particularly in children, were discussed by Dr. C. H. KRÜGER, who gave a comprehensive and practical review of the tonsillar ailments of early childhood. The problems of diagnosis were dealt with by Mr. R. L. SCOTT. Acute follicular tonsillitis and acute septic sore throat were discussed in detail, while chronic cryptic and chronic suppurative tonsillitis were presented as typical chronic affections requiring skill in elucidation. Tubercle, syphilis, keratosis pharyngis, and Vincent's angina were considered in turn. The clinical picture was presented by Mr. J. LÜCKHOFF. The recurring pharyngitis, the accumulated debris in a tonsil lacuna, the lymphatic hyperplasia of an incomplete enucleation, and the frankly diseased tonsil were indicted seriatim and related with the long train of general symptoms and illnesses for which they might be individually responsible. The question of the possibility of the tonsil being an internal secretory gland was discussed. Mr. C. E. JONES-PHILLIPSON followed with a consideration of prognosis. He argued that in the vast majority of acute cases the prognosis was good, but the outlook was bad in all chronic tonsillar infections, chiefly on account of associated sequelae. Acute attacks represented efforts on the part of the lymphoid tissue of the tonsil to produce a natural immunity. If these efforts failed, the tonsil itself then became a positive source of danger. Children starting adolescent life without a healthy tonsil were very seriously handicapped. The prognosis of general systemic disorders resulting from the entry of organisms by way of an unhealthy tonsil was discussed. The end-results of enucleation were briefly reviewed. Mr. PH. A. SMUTS confined himself to the treatment of acute and chronic tonsillitis of the more usual type. He dwelt on the fact that mere hypertrophy was often not a sufficient cause for tonsillectomy, and that small tonsils often emitted unexpected pus on pressure. He argued that tonsillectomy was the only certain cure for chronic tonsillitis, and in conclusion discussed the employment of suction apparatus in throat surgery. Dr. G. W. BAMPFYLDE DANIEL made a contribution to the question of anaesthesia in tonsillar surgery. He condemned the use of chloroform and of closed ether, and gave as his opinion that the anaesthesia of choice was open ether with or without oxygen. Dr. S. E. KARK wound up the discussion, and made some interesting observations on the etiology and significance of adenoid disease.

Dr. W. F. RHOADS, assistant bacteriologist, Union Health Department, then read a paper on the diagnosis of diphtheria in the laboratory, the significance of the Schick reaction, and the divergence of opinion regarding the dosage of antitoxin and its value in dealing with contacts. Mr. P. M. DANIEL, Dr. R. M. MUIR, Dr. W. A. RAIL, Dr. N. O. WILSON, Dr. A. REITH FRASER, Mr. LÜCKHOFF, Mr. SCOTT, Mr. JONES-PHILLIPSON, and Mr. SMUTS took part in the ensuing discussion.

AN International Congress of Municipal Hygiene will be held at Strasbourg from July 15th to 18th. The subscription is 25 francs. Further information can be obtained from M. Albert Paréty, 10 Rue Lavoisier, Paris.

## Reports of Societies.

### PSYCHONEUROSIS AND MENTAL DEFICIENCY.

At a meeting of the Section of Psychiatry of the Royal Society of Medicine on March 13th, Dr. C. HUBERT BOND presiding, a brief discussion took place on the association of psychoneurosis with mental deficiency.

Dr. C. S. MYERS gave details of two cases in point, both of youths of adolescent age who had the minds of children of six or eight. In both cases the influence of an early emotion was pronounced, in one that of fear, and in the other that of a germinating sexual feeling. The original experience (that of a funeral) of the first was not repressed at all, but the youth was very voluble on the subject, and all his talk was coloured by the circumstances of death and the grave. In the second case the original experience was only recoverable in the hypnoidal state, and the removal of the repression seemed to bring about a noticeable improvement. In this case the demeanour of the lad was one of prurient curiosity. Dr. Myers suggested that not only was the mental deficiency responsible for the gravity of the psychoneurotic condition, but that the latter reacted in turn on the slowly developing mind of the mentally defective child and aggravated the deficiency. It was unlikely that mental deficiency was ever direct'y and solely due to a psychoneurosis, but he was convinced that certain cases of mental deficiency could be enormously improved if attention were paid in early life to any concomitant psychoneurotic disturbance.

Dr. HUBERT BOND said that looking back upon his past clinical experience he could not recall that cases of mental deficiency were at all prone to show anything like a psychoneurosis, but certainly cases of that type often showed the psychoses, which were quite definite. It was exceedingly rare for cases of mental deficiency to show anything like true paranoia. On the other hand, so-called moral imbecility had been likened rather to a paranoid condition than to true mental deficiency, and he thought there was something in that argument.

Dr. MYERS, in answer to questions, said that he was inclined to doubt whether, without any mental deficiency or backwardness to begin with, a psychoneurosis, however strong the disturbance, could produce a mental defect.

#### *Genius and Insanity.*

Dr. H. J. NORMAN opened a discussion on genius and insanity. He admitted that a satisfactory definition of either term was difficult, but some relationship between the two things had been long noted. Even Aristotle observed that literary men—poets in particular—suffered from melancholia. Seneca made a similar remark. The so-called demon of Socrates was a hortatory hallucination. More dogmatic writers had stated that genius was really a neurosis. That, of course, was far too sweeping. One of the most satisfactory definitions of genius was by a man who himself was a good example of it, and who eventually committed suicide—B. R. Haydon, the historical painter of the early nineteenth century. Haydon described genius as nothing more than "our common faculties refined to a greater intensity." Huxley said that genius meant innate capacity of any kind above the average mental level, and that the genius among men was in the same position as the sport among animals and plants. To Dr. Norman it seemed that the brain organization of different individuals must be as varied as the facial expression or the muscular development. Certain types of brain must be more prehensile than the rest, have a greater potential for education, be able more readily to acquire knowledge, and have greater capacity for storage. In such brains there must be marked development of the association fibres and ready facility for canalization. In fact, their structure represented the latest development and the highest acquirement, and therefore, as Hughlings Jackson said, they were the most complex, the least organized, and the likeliest to break down. It was, of course, a fallacy to say that because a genius became insane therefore insanity was the cause of genius. That argument was disproved at once by the production of a single genius who was not insane. But it was obvious that in the genius there was instability of the nervous system, resulting in a brain of exceptional calibre for as long as the system maintained its balance, but with a tendency to topple over into insanity. When the insanity occurred, as a rule the genius came to an end. The two did not run concurrently, though they might

alternate. An example of this was Nietzsche. With confusional insanity it would be quite impossible to have any collective mental effort. On the other hand, mania in a mild degree might cause the mental processes to go forward more rapidly. This was observed quite frequently in the early stage of mania. With paranoia, even when persistent, there could be great mental power. But insanity might and often did terminate a period of mental brilliance. It was all a question of unstable equilibrium. There was one other factor involved which it was too early as yet to discuss. It was possible that these changes from mental brilliance to insanity were due to fluctuations in the discharges of one or other of the ductless glands. The fact that epilepsy might be associated with an extraordinary outburst of mental energy was possibly connected in some way with the ductless gland secretions. Dr. Norman believed that the whole question could be approached best from the biological standpoint. Little progress was to be made so long as it was made a matter of pure psychology.

Dr. W. H. B. STODDART doubted Dr. Norman's premisses. He himself had known two great geniuses whose names would be remembered to the end of time—Huglings Jackson and Professor Freud—and both of them were extremely sane individuals. Darwin, Copernicus, and Galileo were undoubted geniuses, but he had never heard their sanity impugned. Nobody doubted that the mind and the nervous system were intimately related, but the point of view of psychology was that the study of the nervous system was not sufficient to lead to a knowledge of psychology, normal or morbid; it was necessary to take, as it were, a dive off the deep end and approach psychology *per se*. Psychoanalysts had found that they were able to explain the psychoneuroses and, to some extent, the psychoses in a way that was not possible by the mere study of the morbid anatomy of the nervous system. In some of the psychoses there was no morbid anatomy; the nervous system was perfectly normal.

Dr. BERNARD HART said that it was out of the question to maintain that genius was invariably insane; yet genius and insanity did occur together in a sufficient number of cases to lead one to search for some connexion. He himself favoured the conception that human beings were, roughly, divisible into two types, the sensitive and the stable, the former reacting continually to outward impressions, the latter able to shut out events and pursue their own steady way. To the extra-sensitive type would no doubt belong the larger proportion of the insane, and also the larger proportion of geniuses.

Dr. JOHN CARSWELL read some autobiographical notes he had collected from the writings of Robert Burns. These gave evidence of a constitutional neurasthenia in the Scottish poet, and of an almost definite melancholia.

### THE INFLUENZA PANDEMIC, 1918.

At a meeting of the Pathological Section of the Sheffield Medico-Chirurgical Society held at Sheffield University on March 22nd, with the President, Dr. RUPERT HALLAM, in the chair, Professor J. G. ADAMI, F.R.S., gave a masterly survey of the development and pathology of the great influenza outbreak of 1918.

Professor Adami at the outset apologized for having no recent work to put before them, as his work as Vice-Chancellor of Liverpool University left him little time for pathology. It had been his task to draw up a report on influenza affecting the troops. That report, finished two years ago, had unfortunately not yet been published, and he was afraid that by the time it was published it might be out of date. The commencement of the great epidemic was usually considered to have been about April or May, 1918. But there were records of sporadic groups of cases often called "purulent bronchitis," for apparently influenzal, occurring as far back as December, in bed and would therefore regard the epidemic as presenting not sure as to the phases in its development: (1) From and discharged her frolier, to May, 1918, sporadic groups of admitted, and two days later as influenzal. (2) From May to uterus was a mass of fibroid of cases, of short duration, com-surface; a fibroid tumour, aboudays' flu." (3) The autumn of jected from the postero-supericvere cases, with an appalling becoming impacted in the pelvis; 1. hysterectomy, and was found to cont. the epidemic there were two months' development. The pati must keep in mind as at first denied the possibility of pregnan. One and the same having missed one period. She was disch. types of lesions in quite well on November 28th.

C. M. ROLSTON.

Antigua, B. W. I.

different stages of the epidemic, because it had acquired increased virulence as the epidemic progressed. Further, secondary invasions were common. In 1916 and 1917 sporadic groups of cases of "purulent bronchitis" were reported and studied by different observers at Etaples, Boulogne, Aldershot, and in America. Fatal cases usually presented the following common features: acute bronchitis and bronchiolitis with purulent exudation, denudation of the lining membrane, and the presence of a small Gram-negative coccobacillus, the air cells being but little affected. In some of these cases Pfeiffer's bacillus was grown in pure culture from the terminal bronchioles, but in most of the cases before 1918 their influenzal nature was not recognized. The pathological lesions were essentially similar to those found in the influenza cases of 1918.

Dealing with the *post-mortem* appearances of the 1918 cases, it was pointed out that one cardinal feature was the regular presence of tracheitis. The larynx and uppermost rings of the trachea usually escaped, but its lower third and bifurcation were almost constantly acutely inflamed. In this area intense purple congestion was followed later by desquamation of the ciliated epithelium. This acute desquamative inflammation appeared to have begun near the bifurcation, and to have spread both upwards and downwards. It was of great significance. Removal of the ciliated epithelium at this spot meant the disappearance of the last effective barrier to the invasion of the lung by inhaled bacteria. This helped to explain the great frequency of secondary invasions in influenza. Further, it was noteworthy that the secondary infections most commonly met with in this disease were by those organisms least susceptible to the bactericidal action of serum. It should be remembered that it was precisely on this area—the neighbourhood of the bifurcation of the trachea—that those bacteria which had succeeded in passing the defences of the upper air passages would impinge.

The difference in the lesions of the lungs found in the last and more severe stage of the epidemic from those found in the earlier and less severe cases was largely due to the increase in virulence of the bacillus, already alluded to. A classical observation of Metchnikoff's illustrated this point. He injected anthrax virus into the two ears of a rabbit; in one ear he injected a strongly active virus, in the other ear an attenuated virus. The stronger virus produced serous exudation and haemorrhages, the weaker one caused cellular infiltration. Corresponding differences were exemplified in the lung lesions of the more severe and less severe cases of this epidemic. In some of the severer cases the lesions seemed brought about by intense toxic action rather than by direct invasion. As regards secondary invasions the pneumococcus, a haemolytic streptococcus, and *Staphylococcus albus* were those most frequently met with.

Summing up his observations, the lecturer considered that the following postulates were justified:

1. One agent, and one only, was primarily responsible for the cases of the pandemic.
2. This agent was the influenza bacillus.
3. In the majority of cases other organisms invaded the lungs and were responsible for many of the conditions found in fatal cases.

He considered that pathologically the cases studied presented a characteristic series of changes which in their totality, in their succession and association, were specific and peculiar to this one disease. He especially emphasized in this series acute tracheitis characterized by denudation, and acute bilateral bronchitis and bronchiolitis, with purulent exudation in the milder cases, sanguineous in the more virulent, and with relatively slight involvement of the air cells. Nothnagel's account of the pathology of the great epidemic in 1890 and the following years corresponded very closely with our later findings.

On the motion of Professor DOUGLAS, seconded by Dr. PLEASANCE, a hearty vote of thanks was accorded to the lecturer.

### INTRACRANIAL AEROCELE.

A MEETING of the Section of Pathology of the Royal Academy of Medicine in Ireland was held on March 2nd, with Dr. GOULDING in the chair, when Sir WILLIAM WHEELER and Dr. E. C. SMITH read notes of a case of intracranial aérocele, with pneumococcal meningitis.

The diagnosis of fracture of the anterior fossa of the base of the skull could be made with certainty. The patient was mentally confused, but was able to swallow and to answer questions with fair

intelligence. The skull was opened over the right frontal lobe. On incising the dura, air bubbled out in small quantities, followed by blood-stained cerebro-spinal fluid. The general blood pressure was low and the brain correspondingly retracted. The frontal lobe of the brain appeared in no way injured, but on free exposure an unusual phenomenon was observed. The patient was breathing heavily; on inspiration the frontal lobe moved upwards from the base of the skull, and fell back again on expiration. This movement of the brain, synchronous with respiration, was well marked, and rendered obscure the natural pulsation. It was obvious that air under some pressure was passing from the nose through a rent in the dura in the neighbourhood of the cribriform plate of the ethmoid and roof of the orbit. It was difficult, however, to understand, with the dura widely opened by the operation, how the force of air was sufficient to raise the brain on each inspiration; yet the movement was indistinct. After operation the condition of the patient improved considerably. Hexamine was administered freely by the mouth, and small doses of hyoscine assisted in controlling restlessness and irritability, which at times increased to a state of violence. Six days after operation the temperature rose to 102° F., the patient became stertorous and the pupils dilated. The larger than the left; both contracted faint conjunctival reflex. Dr. Milne then withdrew by tumour puncture 30 c.cm. of turbid fluid, containing a pure culture of pneumococci. During the withdrawal of the fluid the blood pressure fell from 130 to about 110, and rose again about fifteen minutes afterwards. The temperature continued to rise until it reached 105°, and the patient died of meningitis on the eighth day after operation.

In a paper by Grant of Philadelphia (*Surgery, Gynecology, and Obstetrics*, February, 1923, p. 251) is recorded a case of intracranial aneurysm following a fracture of the skull; Grant had found ten recorded cases of the condition in recent years. The recorded cases suggested that, owing to the danger of infection, the presence of pneumocranium immediately following injury was an indication for operation, and an attempt should be made to close the dural tear. If five or six days had elapsed, when aneurysm was discovered, the sinus might have spontaneously closed, and the policy of watchful waiting for absorption should be adopted. If the possibility of infection could be excluded, the air was relatively innocuous, and would be ultimately absorbed. In making the diagnosis of fractured base of the skull, it was convenient to consider the signs in three classes—certain signs, probable signs, and uncertain signs. If cerebro-spinal fluid escaped from the nose, ear, or mouth, a fractured base was certain; in rarer cases, brain matter might be extruded, which also rendered the diagnosis certain, and a third certain sign might be added—namely, the demonstration of an aneurysm by a skiagram. The points of interest in the case recorded were: (1) the intradural presence of air; (2) the rise and fall of the frontal lobe with respiration; and (3) early dilatation of the pupil on the side of injury without other ocular signs, in the absence of compression, and before the onset of meningitis. Having regard to the high mortality from infection to the meninges in fractures of the base of the skull communicating with the external air, and notwithstanding the general trend of opinion in favour of operation, it seemed questionable whether treatment along conservative lines would not be followed by better results.

Dr. E. C. SMITH exhibited the specimens, and the case was discussed by Dr. CROFTON and Dr. WIGHAM.

Dr. J. H. POLLOCK read (1) a note on an unusual case of pneumococcus infection, with abscess at the root of the aorta, and (2) a note on pernicious anaemia, illustrated by the records of several cases treated by blood transfusion.

Dr. CROFTON read a paper on the treatment of a case of uric acid calculi by therapeutic immunization; by immunization against the microbes isolated from the skin and from the intestinal tract he was able to reduce the production of urates in the body.

Sir WILLIAM WHEELER drew attention to the flooding of the caecum and lower ileum with micro-organisms after purgation. He was of opinion that the presence of bacilli in the urine was consistent with health, and might be indicative of action of the healthy kidneys, although later, in the presence of added pathological conditions, they might lead to disease.

At a meeting of the Bath Clinical Society, held at the Royal United Hospital, Bath, on March 2nd, with Mr. W. G. MUMFORD, President, in the chair, Dr. H. H. BUTCHER read a paper on tropical abscess of the liver. He laid stress on the number of amoebic carriers among soldiers returned from service in the East, and was practically certain that there would be an increased incidence in the disease during the next few years. The causative protozoon was described and the methods of identification outlined. After tracing the path of the pathological features of the disease, Dr. Butcher passed on to an account of the symptomatology, and finally to the problem of differential diagnosis. Cases and specimens were shown by Dr. S. MARLE, Dr. V. M. COATES, Mr. A. L. FULLER, Dr. R. WATERHOUSE, Dr. F. G. THOMSON, Mr. C. H. TERRY, and Dr. R. G. GORDON.

### REMEMBERING AND FORGETTING.

In a volume entitled *Remembering and Forgetting*,<sup>1</sup> Professor T. H. PEAR discusses the psychology of some of the most interesting facts concerning memory. In the earlier chapters he explains the processes of impression, retention, and recall; gives an account of after-sensations, primary memory images, and revived images; indicates the differences between sensations and percepts, and percepts and images; and discusses the functions of the image. These data constitute, of course, the usual subject-matter of conventional psychology, but the author deals with them along modern lines. He devotes particular attention to the problem of imageless thought and kinaesthetic sensations; he criticizes the extreme behaviourists who would deny the existence of the image, and aptly compares them to "the countryman whose surprise on seeing a hippopotamus caused him to declare that there was no such animal" (p. 62). The consideration of images leads up to psychology of dreams, a subject to which four chapters are devoted. As the author observes, the structural aspects of the dream provide a valuable way of studying the relation between image and meaning. The dream affords a perfect example of the alteration of values, for in it the images increase, decrease, and modify their values and functions very much as material wealth in war time. The dream theories of Freud and Rivers are outlined, and an endeavour is made to show that the processes of condensation, dramatization, and secondary elaboration are operative in determining the structure of thought in waking as well as dream states. Here, as throughout the book, the author's aim is to link up ordinary psychology with the recent developments of medical psychology.

A chapter is devoted to the important and difficult subject of forgetting, and, after discussing Freud's theory of repression and the views of other psychologists, some new and useful suggestions are made in regard to a provisional classification of forgotten experience. The volume contains an appendix dealing with subjects which serve to illustrate many principles laid down in the main part of the book. Professor Pear has written a book in which the student of psychology will find much of interest and value.

### PROBLEMS OF PRACTICAL SURGERY.

WHEN Mr. BURROW undertook to write a book entitled *The Mistakes and Accidents of Surgery*,<sup>2</sup> he shouldered a great responsibility. Fair and accurate criticism is at all times a delicate task, but where it is applied to problems so many-sided as those the surgeon has to consider when dealing with the diagnosis of conditions amenable to surgical treatment and the best way of carrying out that treatment, it becomes so extremely difficult that anything like dogmatism is out of place. The title is perhaps a little unhappy. It suggests that the volume deals with those unfortunate errors of judgement or manipulation to which all are liable, and it was no doubt on this supposition that the book was seized upon by a certain section of the lay press to furnish material for sensational articles with scare headlines. The author's main intention, however, seems to have been to discuss certain moot questions and only incidentally to refer to errors or accidents. "Mistake" is a strong word, and before accepting the view that it is properly applied to some particular course of action several things are necessary. It is, of course, conceivable that the departure from custom may be an improvement; but apart from this, when a procedure is criticized it must at the very least be shown that what was done was contrary to the general consensus of surgical opinion. With a great deal of what Mr. Burrows has to say most surgeons will agree, but there are statements and inferences with which many of them will not agree.

The book is arranged in sections according to the various parts of the body, and, as each portion comes under review, attention is drawn to various acts of omission or commission which Mr. Burrows regards as errors.

We come first to what the author holds to be errors in connexion with head injuries. He deprecates the application

<sup>1</sup> *Remembering and Forgetting*. By T. H. PEAR, M.A., B.Sc. London: Methuen and Co., Ltd. 1922. (Cr. 8vo, pp. xii + 242; 9 diagrams. 7s. 6d. net.)

<sup>2</sup> *The Mistakes and Accidents of Surgery*. By Harold Burrows, C.B.E., M.B., B.S., F.R.C.S. London: Baillière, Tindall, and Cox. 1923. (Demy 8vo, pp. viii + 472. 10s. 6d. net.)

of hygienic measures to the external auditory meatus in fracture of the middle fossa of the skull communicating with the middle ear; but we question whether the majority of surgeons would agree with him. It would seem, too, unnecessary to sound a warning against opening the dura when it bulges into a trephine opening; this is but a natural event, and as such it is recognized. Perhaps Mr. Burrows would imply some quantitative consideration, but in a critical treatise there is a duty to be exact. In the same connexion the advice that a bulging dura calls for lumbar puncture is of doubtful validity.

There is a chapter dealing with the errors which may arise in connexion with tuberculous glands in the neck, and many surgeons will be surprised to be told that the correct routes of access to the glands are obtained by incisions, "one along the front border of the sterno-mastoid for exposure of the anterior triangle, and the other along the hinder border of the muscle to open up the posterior triangle." We tremble for the intervening skin.

Mr. Burrows no doubt realizes that he is living in a glass house, and, though he has defied the advice of the proverb, we have no wish to throw stones; but we would remind him that the sterno-mastoid artery which accompanies the spinal accessory is not a branch of the superior thyroid, but is derived from the occipital, and that a hæmorrhage which occurs on the day succeeding operation is a reactionary and not a secondary hæmorrhage. When Mr. Burrows is engaged in criticism it is unwise to give the enemy an opportunity of hoisting him with his own petard. Mr. Burrows advises that the best way in which to define the internal jugular vein is "to free the digastric muscle and to retract it upwards." This piece of advice must be regarded as dangerous; it may indeed be fertile in disaster to the inexperienced operator.

A great deal of debatable matter is introduced into that portion of the book which treats of goitre; the section dealing with exophthalmic goitre contains the statement that "to operate for Graves's disease often is malpraxis." This, if we understand it aright, for the sentence is not clearly expressed, cannot be accepted as a good criticism, and the use of the term "malpraxis" is surely a mistake. We find it stated that "Tetany . . . probably is attributable to the removal of an excessive amount of the gland tissue"—there is no mention of the parathyroids; and again, crushing of the isthmus or the lateral lobe is condemned as an unnecessary and perhaps dangerous practice, Mr. Burrows maintaining that "it is better to cut through this structure with a sharp knife"; the conflict of opinion on this point is probably correspondingly acute. We dislike the advice that free drainage is necessary after thyroidectomy in order to remove the "surprisingly large" amount of colloidal material which may escape from the wound.

In speaking of tracheotomy it is said that "it takes a considerable time (from ten to twenty minutes) to kill a healthy man by suffocation"; many surgeons have had painful experience of the incorrectness of this pronouncement. The soundness of Mr. Burrows's advice that division of the isthmus of the thyroid gland is to be recommended as a routine step in the operation of tracheotomy is open to question. We would remind him also that his condemnation of the rigid tracheotomy tube is not generally accepted.

In discussing epithelioma of the tongue no mention is made of the importance of removing the omohyoid glands, and the risk of opening into the mouth during the dissection of the cervical lymphatics seems to be exaggerated. The section dealing with pleural effusions contains a great deal of debatable matter. In the operation for removal of the breast the statement that "attempts to save the subscapular nerves, for example, will not only take up precious time but may impair the thoroughness of the clearance in a vital situation" surely demands revision; many surgeons would regard it as very dangerous advice, especially for the beginner.

It is unnecessary to elaborate any further disputable statements; sufficient has been said to demonstrate that they are by no means sparse. Our considered opinion is that this book has failed in its object—if it is a criticism of the methods and judgement of others, it must be accepted as an individual criticism, and therefore by no means infallible. We do not think that any useful purpose has been served by its publication, because the place which it was intended to take is already occupied by the majority of our reliable textbooks, while many of the individual opinions which it expresses are open to serious criticism.

## PULMONARY TUBERCULOSIS.

To the third edition of the book on *Pulmonary Tuberculosis*, by Dr. FISHBERG of New York, two new chapters have been added—one dealing with the relations between pulmonary tuberculosis and the rest of the body, the other treating of the medico-legal aspects of the disease. The former subject is of especial interest, as it has hitherto been quite inadequately considered. So much attention is apt to be devoted to the intensive study of the lung lesion that its effect on the physiology of the body as a whole, and the converse systemic reaction upon the focal area of disease, has only too frequently been neglected. As an example of such a reciprocal influence the author remarks: "There seems to be a distinct antagonism between tuberculosis of the lungs and that of other organs which is not appreciated to the extent it deserves; its diagnostic and prognostic significance cannot be overestimated." Statistics relating to the percentage incidence of tuberculosis in other parts of the body in phthisical patients are given in illustration of this statement. On the other hand, lymphatism, chronic bronchitis, the arthritic diathesis, hyperthyroidism, and diminished activity of the gonads, amongst others, all tend to exert an inhibitory effect on the development of pulmonary tuberculosis, while other conditions, such as congenital hypoplasia of the heart, pulmonary stenosis, measles, whooping-cough, and puberty seem to favour its evolution. The influence of pregnancy is treated of very fully and in an eminently rational manner. Besides the introduction of additional subject-matter portions of the book have been rewritten so as to bring it thoroughly up to date. We can commend this work very highly; its original observations, its dispassionate method of presentation, and its careful foundation upon ascertained fact, serve to place it amongst the few genuinely authoritative books on pulmonary tuberculosis.

In *A Simple Treatment for Tuberculosis* Dr. OWEN F. PAGET describes his success in the cure of phthisis and of other tuberculous affections, such as those involving glands, bones, joints, and the genito-urinary system, by the nasal insufflation of tuberculin B.E. Severe febrile cases are given 1/6000 mg., subfebrile cases 1/500 mg., and mild afebrile cases 1/40 mg. The bacillary emulsion is made up in the form of a powder, which is introduced by an insufflator into the nostril of one or both sides on alternate days. Care is to be taken to direct the powder upwards so as to reach the region of the ethmoid and superior turbinate bones. The usual length of treatment appears to be about three months, and during the latter part of the period the treatment is accompanied by breathing exercises designed "to open up disused and formerly inflamed bronchioles and alveoli, and to assist the absorption and resolution of consolidated lung, to break down pleuritic adhesions, and to educate the patient in properly expanding his lungs and developing his chest." This treatment appears to be founded upon a belief that it is one of the special functions of the epithelial cells of the nasal mucosa to form antibodies to the tubercle bacillus. The author's original observation was made on a patient suffering from advanced phthisis. Despairing of offering him relief, he advised him to dry his sputum in the sun and sniff the powdered residue up his nose. This case responded in a most remarkable manner—so remarkable as to convince the author of the peculiar immunological properties of the nasal epithelium. To establish this he investigated the skulls of certain animals—the hyena, wild deer, leopard, and sheep—and found that they had very large noses. Now these animals do not suffer from tuberculosis, and the inference drawn was that this insusceptibility was due to the extraordinary size of their noses. The author accepts the estimate that 10 per cent. of human beings are not subject to tuberculosis, and that only 10 per cent. of people breathe through their noses, and seems disposed to conclude that nose-breathing protects against tuberculosis. We have no doubt of the author's sincerity, but is it necessary to point out that, before such inductions can be made, certain premisses must first be substantiated? In the first place no statistics are given to show that tuberculosis is commoner amongst mouth-breathers than amongst nose-breathers. Actually we believe there is a considerable amount of evidence to the contrary. The commonest cause

*Pulmonary Tuberculosis*. By Maurice Fishberg, M.D. London: H. K. Lewis, 1922. pp. xiv + 231; 23 plates, 122 figures. 42s. 6d.  
*A Simple Treatment for Tuberculosis*. By Owen F. Paget, M.D. London, Bombay, and Sydney: Cassell's and Co., Ltd. 1922. 10s. 6d. pp. xxiii + 20; 7 figures. 5s. net.

of mouth-breathing in children is the presence of adenoids, yet, according to Fischberg, it is uncommon for children with adenoids to develop tuberculosis. Again, the animals that he mentions are living in a more or less feral state. It is not to be expected that they should suffer from tuberculosis, any more than barbaric man in his uncivilized condition suffers from it. If Dr. Paget were to take the case of domesticated animals and to demonstrate that there is a very definite correlation between the size of the nose and the resistance to tuberculosis, he would have better grounds for making his inference. With regard to clinical results, he states that of 500 cases of tuberculosis and suspected tuberculosis amongst the Australian Forces not one failed to improve under treatment. In the first fortnight before treatment commenced there were three deaths. In the following ten months with treatment there were only two deaths. No data are given as to the number proved bacteriologically to be suffering from tuberculosis, nor as to the stage of disease, nor the extent of lung affected. How many of these patients, we may ask, were actually tuberculous? We have it on the authority of the French that in about 70 to 80 per cent. of patients admitted to their military hospitals as suffering from tuberculosis the diagnosis was wrong. It is plain that the author has rather a leaning towards the diagnosis of tuberculosis. He says in effect that, lacking positive evidence of other disease, 90 per cent. of the affections of the nose, tonsils, pharynx, and lungs are tuberculous. Later we read: "The mysteries of physiology and pathology are unlimited. But how extraordinary and marvellous is the chain of events whereby a few insufflations of 1/10,000 mg. of tubercle bacillary emulsion on the epithelial cells of the ethmoidal region can bring about the resolution of a pathological exudate in the alveoli of the lungs!" Very extraordinary and very marvellous! We have no desire to disparage this treatment. It may be good, or it may be valueless; we do not know. Incidentally, there is a certain amount of experimental evidence which suggests that the mucosa of the respiratory tract may play a part in antibody production. But, even though this treatment should subsequently prove efficacious in every form of tubercle, we are bound to say that the case for it, as stated in the volume, is not convincing, and that the evidence in its support is not adequate.

#### EAR, NOSE, AND THROAT.

DR. GEORGES PORTMANN, Chef de Clinique in the department of Oto-Rhino-Laryngology of the Faculty of Medicine at Bordeaux, has produced, under the title *Consultations Oto-Rhino-Laryngologiques du Praticien*,<sup>5</sup> a volume which should be valuable not only to the specialist but also to the practitioner in dealing with the medical treatment of maladies which are of daily occurrence both in general and special practice. The medical aspect of this specialty, which in recent years has become more and more surgical, is a little apt to be neglected, and Dr. Portmann is to be congratulated on having presented with all the method and precision of the French school a book of this kind at the present moment. Prescriptions and alternative methods of treatment are given for every condition which occurs at all frequently in practice, and, what is even more important, exact instructions for their application, together with indications and contraindications. There are sections on incompatibility of drugs in ordinary use in otology and laryngology, on vaccine therapy and on the general therapeutics of the ear and throat. There can be no hesitation in recommending this book, for it cannot fail to be of great help in dealing both with those innumerable minor maladies which are distressing to the patient and difficult to treat, and also with conditions where surgical treatment is not indicated. Those details, which so often turn the scale between success and failure, are here given in abundance, and the book is one which will be consulted freely and with satisfaction by those for whom it is intended.

The appearance of six editions of Dr. WENDELL C. PHILLIPS's well known textbook on *Diseases of the Ear, Nose and Throat*<sup>6</sup> in the course of eleven years is evidence of its popularity. Dr. Phillips gives within a volume of moderate size an adequate account of these subjects, and the book can

safely be recommended to anyone desiring to find them all included under one cover. About half the book is devoted to diseases of the ear. Then follows an excellent description of the influence of general diseases upon the ear, nose, and throat, and the remainder is divided about equally between the nose and throat. The author states in his preface that it has been his "continued desire to thoroughly Americanize this volume." In this he has succeeded, though he refers freely to certain British textbooks, especially that of Parker. The result is that some of his teaching differs materially from that accepted in this country. For example, in the treatment of intrinsic laryngeal cancer thyrotomy only receives the barest mention, and laryngectomy is strongly advocated for the majority of cases. The operation is described at great length. The pessimism of the author, too, on the subject of extrinsic cancer of the larynx, grave as that disease may be, scarcely does credit to the achievements of modern surgery. One of the greatest merits of the book is the excellence and profusion of the illustrations. It is also singularly free from misprints and slips of the pen. Herzog, referred to on page 427, is presumably Heryng, and the descriptions of the illustrations of recurrent laryngeal nerve paralysis on page 809 require correction. In spite of the abundance of textbooks on these subjects, the present edition will without doubt hold the place that previous editions won.

#### NOTES ON BOOKS.

IN her small handbook, *The Writing of Medical Papers*,<sup>7</sup> Mrs. MELLISH has epitomized, for the benefit of others, some of her experience as editor of the Mayo Clinic publications. Her purpose is "to help untrained and partly trained writers to prepare for publication articles that will convey information with brevity, accuracy, and clearness, and adhere to the accepted forms of present-day usage." The work consists of twenty short chapters, a very full list of standard abbreviations for the names of medical periodicals, and a comprehensive index. Each chapter closes with a few clear-cut dogmatic sentences, giving the gist of what has gone before. Thus the teaching of Chapter XIV on the choice and arrangement of references is summed up in four sensible rules which we could wish written over the mantelpiece of every one of our contributors:

"Verify all references; be positive that they are complete and accurate.

"Index all articles when reading or abstracting.

"Refer to original articles. Do not give references from previous references.

"If an abstract is referred to, state the fact that it is an abstract."

The author's own advice is reinforced by a great many quotations, and in particular by liberal extracts from the second edition of Sir Clifford Allbutt's *Notes on the Composition of Scientific Papers* (the third edition was reviewed in our issue of March 10th). All the quotations are printed in small type, and the author of each extract is indicated by a very small numeral corresponding with a bibliography at the end of the book. Where the extracts are long—and some of them occupy several pages—it is often difficult to be sure where one quotation ends and another begins; it would be much better, we think, to space out each piece of borrowed advice, and (at the risk of tiresome repetition) to show more plainly the source of each. Again, the first of Mrs. Mellish's five admirable maxims printed on page 114 is: "Be exact in copying quotations"; but has she quite lived up to that advice on page 52? These small criticisms apart, we find something to commend in almost every chapter. Some of the many "Don'ts" are, we should hope, unneeded by British practitioners, and a few of the typographical rules are at variance with English practice; but it is only natural that American usage should be observed in a book printed in Philadelphia.

*The Rescue Man's Manual*<sup>8</sup> is the title of a handy guide, by Mr. ARTHUR B. CLIFFORD, for those engaged in rescue work at collieries, irrespective of the apparatus to which they are accustomed. The author insists that there can be no real substitute for practical training, but he intends his book to fill the gaps in the intervals between the practices, which now take place only four times a year. Although it is not intended directly for them, medical practitioners in colliery districts will find this little book, which is clearly, simply written, of considerable interest.

## THE LAMENESS OF LORD BYRON.

At the social meeting of the Royal Society of Medicine last week (March 21st) Dr. H. C. Cameron gave a short address on the mystery of Lord Byron's lameness. After some introductory remarks Dr. Cameron referred to the fact that while Byron was indifferent to charges of immorality and irreligion, it was far otherwise with regard to his physical disability. To his lameness Byron was exquisitely sensitive; he never for a moment forgot it, and it poisoned his whole life. In some autobiographical notes he tells how once, when he was a child, his mother in one of her fits of fury called him a lame brat, and how he quickly retorted "I was born so, mother." Three years before his death he wrote, at Pisa his tragedy *The Deformed Transformed*; the first words of the play were the cry of the mother, "Out, hunchback," and again came the answer, "I was born so, mother."

It was commonly alleged during his lifetime that Byron had a club-foot, but it was, Dr. Cameron said, a curious circumstance that friends and enemies alike were uncertain as to which foot was deformed. Moore, his biographer, who knew him well; Galt, also his biographer, and companion on one of his Eastern tours; Lady Blessington, and the Countess Albrizzi, both great friends of his, never could make up their minds which foot was deformed. His boxing instructor, Gentleman Jackson, the pugilist, thought it was the left. His mother, writing to her sister-in-law about taking the opinion of John Hunter, stated definitely, "It is the right foot." Mrs. Leigh Hunt, who with her husband was for long Byron's guest, thought that the left foot was shrunken, but that it was not a club-foot.

Sheldrake, an instrument maker and bone-setter in the Strand, affirmed that Byron, when in his 20th year, consulted him. In 1827-28 Sheldrake wrote a series of letters to the *Lancet*, and in one of these, published on September 20th, 1828, entitled "Lord Byron's Case," he gave drawings of what he alleged to be the cast of Byron's foot. It represents the left foot. The woodcuts, Dr. Cameron thought, were suspiciously like those which illustrated the article on club-foot in every textbook of the time. He rejected Sheldrake's evidence altogether. Stendhall and Hobhouse both said it was the right foot that was deformed, Countess Guiccioli that it was the left. These contradictory statements appear surprising if Byron really had, as was generally believed, a club-foot.

By the kindness, Dr. Cameron continued, of Mr. John Murray, the present head of the great firm which published all the poet's works, we have here to-night two surgical boots made for and worn by Byron as a boy. They are both for the right foot, but I would have you especially observe that they have been made for a foot which is both long and slender and which in no way resembles a club-foot. It is significant of the great interest which was taken in the question of Byron's lameness at the time that after his death the lasts on which his boots were made were thought suitable objects for exhibition in a public museum. Mrs. Wildman, whose husband had purchased Newstead Abbey from the poet, found them and sent them to the museum at Nottingham. There they were discovered after long search in 1897 by Mr. James Ward of that city, stowed away in a drawer with the original paper still attached to them:

These are the lasts upon which Lord Byron's shoes were made by Mr. W. Swift of Southwell. The last pair made upon them was on May the seventh 1807.

Contributed by W. Jones, Southwell.

Stamped on last: CHAULK, Princes St., Drury Lane.  
Stamped on the block: W. Swift.

And the plot begins to thicken—the lasts show feet which are symmetrical and well formed. By the kindness of the curators of the Nottingham Museum I am able to show them to you and to reproduce the photograph.

In 1858 Edward John Trelawny (then in his 66th year) published his book *Recollections of the Last Days of Shelley and Byron*. He had been the friend and companion of both, but Byron wrote prophetically that Trelawny could not tell the truth to save his life. In his book he described minutely the pains he took to satisfy his own unhealthy curiosity and that of the British public. Immediately after Byron's death Trelawny says he hurried to Missolonghi, where lay the embalmed body of the poet; watching over it he found Fletcher, the poet's valet. To get rid of him Trelawny feigned faintness and asked for a glass of water; when the faithful Fletcher had departed on the errand Trelawny hurried forward, drew back the black pall and the white shroud.

"I uncovered the Pilgrim's feet and was answered—the great mystery was solved. Both his feet were clubbed and his legs withered to the knee—the form and features of an Apollo, with the feet and legs of a sylvan satyr."

That, Dr. Cameron continued, was just what the public expected to hear and wanted to hear. But when Trelawny was an old man (in his 86th year) he republished his book with some additions and one striking alteration. We read again of the trick played upon the servant and of the uncovering of the feet, but this time Trelawny wrote:

"I uncovered the Pilgrim's feet and was answered—It was caused by the contraction of the back sinews which the doctors call tendon Achilles that prevented his heels touching on the ground and compelled him to walk on the fore part of his feet; except this defect his feet were perfect."

"I think that Trelawny as he drew near death and as he felt more and more the responsibility that was his as the solo survivor of the actors in the scenes he describes, could not go down to the grave with the lie unwitdrawn, and that he rewrote his book that he might ease his conscience."

It was, Dr. Cameron went on to say, difficult to assess the degree of Byron's lameness; while all admitted the existence of a definite impediment, it was nevertheless clearly of slight degree and compatible with feats both of strength and endurance. It did not prevent him from playing cricket for Harrow against Eton on August 12th, 1805, though cricket, even an Eton v. Harrow match, was perhaps hardly the strenuous thing it has since become. It appears from Lillywhite's *Cricket Scores and Biographies of Celebrated Cricketers from 1745 to 1826* that Eton won by an innings and two runs. In the first innings Harrow made 55 and Eton 122. Harrow's second innings produced 65. Byron seems to have gone in seventh in both innings, making 7 in the first and 2 in the second. He was caught in both innings. Of the players in

this match Lloyd, who was head of the school for that year, told Dean Merivale, who has repeated the statement in his *Recollections*, that "Byron played in that match and very badly." He should never have been in the eleven if my counsel had been taken. "Caustic comment," Dr. Cameron observed, "from one who failed to score in either innings." In some manuscript reminiscences left by a schoolfellow (Shakespeare) it is stated that "in a match of cricket played at Lord's ground Lord Byron insisted upon playing and was allowed a person to run for him, his lameness impeding him so much. Lord Stratford de Redcliffe as an old man used to recall how he had seen Byron playing in this match, 'a moody-faced boy dismissed for a small score.' Possibly the recollections of these old gentlemen were tinged with prejudice. A few days

Photograph of the lasts on which Byron's boots were made. Reproduced by permission of the Curator of the Nottingham Museum.

after the match Byron wrote two letters to intimate friends from which it appeared that he had persuaded himself that he had made eighteen runs—he called them “notches”—“more than anyone except Ipswich.” His swim across the Hellespont was, the lecturer said, too famous to make it necessary to say more than that Byron was in the water for one hour and ten minutes.

The concluding passages of Dr. Cameron's address were as follows:

#### THE NATURE OF LORD BYRON'S LAMENESS.

What, then, was the nature of this extraordinary lameness which was so elusive that one-half of mankind located it in the one foot and half in the other, which embittered the poet's whole life, which excited so much public interest, and which permitted such athletic success? Is it permitted a hundred years after the death scene at Missolonghi to attempt a diagnosis? In that long space of time we have learnt a great deal of the nature of injuries acquired by the infant at the moment of birth. Forty years after Byron's death Little, the great orthopaedic surgeon, introduced as a guest at a meeting of the London Obstetrical Society, read a paper, thereafter famous, in which he described a form of injury to the brain, occurring at birth, which results in a stiffness and awkwardness usually confined to the lower limbs. Because of delay in the establishment of respiration and of the consequent asphyxia a haemorrhage takes place over the area of the brain which

A brain showing meningeal haemorrhages from an infant who lived twenty-six hours. Reproduced from Dr. Herbert Spencer's paper on Children in the *Transactions of vol. xxxiii (1891).*

presides over the voluntary movements of the legs. The gait of “Little's disease,” as it has ever since been called, is stiff and awkward. At rest or during sleep nothing amiss is to be noted, but when a voluntary act such as walking is attempted the limbs are gripped in a kind of spasm. The knees tend to be pressed together and the body rises stiffly on the toes. Though progress may be slow the movement in each step is exaggerated, as though the sufferer were running in a curious stiff and jerky fashion. The feet and legs are, of course, well and normally formed, though during action the tendo Achillis may be prominent.

Trelawny alone attempts a detailed description of Byron's gait. It is such that it accords with the hypothesis of Little's disease and with no other. “During his brief and brilliant career in London it was noticed by his friends that

to hide his lameness he always entered a room quickly, running rather than walking, and stopt himself by planting his left (the comparatively sound) foot on the ground and resting upon it. On the rare occasions on which he was seen walking in the streets, it was observed that he moved with a peculiar sliding gait rather than the easy lounge of a fashionable—in fact with the gait of a person walking on the balls and toes of his feet and doing his best to hide the singular mode of progression.”

It is characteristic of Little's disease that the sufferer learns gradually to overcome his defect. The difficulty and awkwardness may remain to some extent throughout life, but by constant practice agility and control steadily improve when

infancy and early childhood are past. In early childhood Byron was carried from doctor to doctor. He was treated in turn by John Hunter, Dr. Livingstone of Aberdeen, the celebrated Dr. Matthew Baillie, Dr. Laurie of St. Bartholomew's Close, as well as by the bone-setters Sheldrake of the Strand and Lavender of Nottingham. The treatment of the last named was so drastic that it came near not to curing but to causing permanent deformity.

The poet himself states frequently that his lameness was caused at his birth. Of the actual circumstances of his birth we know little. It took place, according to Hanson the family solicitor, in the back drawing-room of No. 16, later No. 24, Holles Street, Cavendish Square. He was born with a caul, which was purchased by Hanson and given to his brother, Captain Hanson, R.N. Perhaps because it was Byron's it brought none of its proverbial luck. Captain Hanson's ship went down with all hands off Newhaven two years later.

Finally, it may be noted that sufferers from Little's disease are prone to convulsive seizures like those of epilepsy, and that Byron, at least towards the end of his life, suffered repeatedly from such attacks.

I close by suggesting to you that we have found the solution of this mystery of Lord Byron's lameness which so excited the interest of our grandfathers, and found it in the back drawing-room of a little house which stood within a few yards of this hall, where one hundred and thirty-six years ago the baby Byron first, but too slowly, drew his breath.

## THE PROBLEM OF DRUG ADDICTION.

### DEBATE AT THE MEDICO-LEGAL SOCIETY.

LORD JUSTICE ATKIN presided over a meeting of the Medico-Legal Society on March 20th, when a paper was read by Dr. H.A. BURRIDGE, lecturer on forensic medicine and toxicology at King's College Hospital, on the subject of State effort to rescue drug victims, with special reference to the Dangerous Drugs Act.

#### British and American Practice.

Dr. BURRIDGE contrasted British and American methods of dealing with drug addicts. On this side of the Atlantic the American principle of correlating treatment with penal repression had not been followed, nor had there been sufficient survey of drug addiction before legislative enactment. Not only the medical but the legal mind in the United States regarded the drug addict as a sufferer rather than a criminal. He gave some figures to show the large extent of drug addiction in America.<sup>1</sup> Among other proofs, it was stated that in the Court of Special Session in New York County at least one-tenth of the business was concerned with drug addicts, and if offences which were really the result of drug addiction were included the proportion was much greater. In America any magistrate, on a complaint being made, might commit the drug addict to a State, county, or city hospital. Dr. BurrIDGE cited particulars of some recent prosecutions in this

country to illustrate the inequalities, injustices, and irrelevantances of the English law, and he criticized several points in the Dangerous Drugs Regulations, particularly those relating to prescribing and to record-keeping by medical men. He regretted that those who initiated recent legislation and the proposed amending legislation should have caused confusion and created stumbling-blocks simply by their failure to take the general practitioner into counsel. This Dangerous Drugs Act seemed as if it might become known as the “Dangerous to Doctors Act,” and half the members of the Medico-Legal Society might presently be employed in keeping the other half out of prison. He pleaded for the setting up of a proper advisory committee to thrash out the necessary amendments to the Act of 1920 as suggested by actual medical experience, and thus the sudden eruptions of fresh regulations at the instance of a Government department might be avoided. The American authorities (Dr. BurrIDGE continued) had tackled the subject of treatment in a way to evoke admiration. The result of an official inquiry in the United States might be broadly stated as being (1) that there was no known specific remedy for drug addiction, and (2) that the cocaine habit more readily responded to treatment than the narcotic habit. The best results were obtained when the victim was in some kind of custody, not in prison, but in a controlled sanatorium. The American experts regarded heroin as the most dangerous drug in the category, especially because of its

<sup>1</sup> In an American White Paper lately issued the number of drug addicts in the United States is given as 1,388,600, their ages ranging from 12 to 75.

attractiveness to the young. The heroin habit was said to have grown to extremely large proportions in America, and the average age of its victims in the area covered by one inquiry was 22. Some experts contended that without injury to medicine this drug might be banished altogether. Dr. Burrage thought it of first importance, in approaching the question of treatment, to endeavour to discover the mental and moral condition of the addict. A person struggling alone to loosen the bonds of the drug habit was engaged in a task like that of Sisyphus himself. Until self-respect had been re-established there was no hope of cure. It was an absurdity if not a crime to commit these people to prison, where the last shreds of their self-respect would be lost. His suggestion was that they should be committed by the magistrate to a home, preferably a farm, and that, perhaps six weeks later, they should be brought before the same magistrate, who would sit with a medical assessor, and evidence would be given by a medical officer of the institution to which they had been committed. Upon the decision of the magistrate they could be released on their own recognizances or committed for a further period. He deprecated heavy fines and prison discipline, unrelieved by remedial treatment.

#### Classification of Addicts.

Sir WILLIAM WILCOX said that drug addicts fell into two classes. The first were the unfortunate people who had become victims possibly owing, in the first instance, to a medical prescription or to their own curiosity. These people were intensely concerned at their state, and wandered about from one doctor to another, thereby giving rise to the impression that they were more numerous than was actually the case; many of them were originally mentally unstable. Any treatment of this type of case, unless under strict supervision and control, was quite futile, but with such safeguards the prognosis was not so unfavourable as was popularly supposed. Sir William Wilcox suggested that there might be some kind of State certification of such persons, somewhat similar to that employed in the case of persons of unsound mind. Another class of drug addicts were degenerates who haunted disreputable resorts and lived on a succession of debased so-called pleasures. These cases were numerous, and were not often seen by medical men, but a lurid light was occasionally thrown upon their existence by some revelation in the police or coroners' courts. It was well to remember that the drug habit became really dangerous when the drug was taken hypodermically; it was less dangerous when taken by the mouth. He agreed that the regulations under the Dangerous Drugs Act were very irritating to the general practitioner, but he thought that they would be gradually revised in the light of experience and made more workable. Of course the underlying evil would never be countered until not merely the sale and distribution of the drugs but their production was under control.

LORD RIDDELL said that the clauses of the Dangerous Drugs and Poisons (Amendment) Bill now before Parliament appeared to be far too complicated and to impose an undue burden on the medical practitioner, but it would be the fault of the medical profession itself if it did not get the bill altered. The medical profession had only to say that these proposals were unworkable and they would not go through.

In some further brief discussion one or two speakers made the point already put forward in the leading article in the BRITISH MEDICAL JOURNAL of March 17th (p. 477), that in the Dangerous Drugs and Poisons (Amendment) Bill a discrimination was made between registered medical practitioners in actual practice and registered medical practitioners not in actual practice. It was argued that among the latter, strictly speaking, must be included medical officers of health and holders of other appointments.

MR. PERRINS, of the Home Office, said that he had looked up the records in his department and had found that only seventeen addicts had been prosecuted since the Act came into force in 1921, and of these he did not think that more than six were sent to prison. Most of them were sent directly to a home, or were remanded for that purpose. The heavy penalties were reserved for the people who deliberately trafficked in drugs. With regard to the requirement that only doctors engaged in actual practice should be allowed to prescribe, this was inserted as a safeguard against those few members of the profession who were "down and out," having lost their practice for some reason, and who might try to make a living by prescribing for addicts. He spoke only as an individual, not as a representative of his department.

#### A Judicial View.

THE PRESIDENT said that he believed the medical profession as a whole was deeply conscious of the evil involved in the drug traffic and sincerely anxious to do everything it could to mitigate that evil. He could not help thinking that the true way of setting to work was to trust medical practitioners, not to create difficulties in their path when they were engaged in the ordinary bona fide practice among their patients, but to provide for the most severe penalties upon doctors who evaded the provisions of the Act for the purpose of supplying drugs improperly to addicts or obtaining them improperly for themselves. If the medical profession agreed to this very proper line the authorities might be induced to modify some of the more irksome provisions with regard to dispensing and record-keeping. Dr. Burrage had chiefly praised in the American procedure the efforts made for the cure of addicts by sending them to institutions; but, whatever might be the case in America, in this country there were not enough institutions for this purpose, and it would be impossible to deal with this matter until the State in the first place had seen to it that there were institutions sufficient in number and large enough in accommodation to which the courts could in cases of necessity commit the persons who were brought before them and were proved to be addicts. This had not been a very popular form of procedure so far in this country, and he rather trembled at Sir William Wilcox's suggestion that some such method might be adopted as was at present in force for certifying lunatics. Another Board of Control would be required, together with an elaborate system, involving dangers which might in the end defeat the object in view. Possibly it would suffice for the Ministry of Health to supervise and encourage the growth of private institutions, which might perhaps be assisted from public funds.

A good deal had been said (Lord Justice Atkin continued) in criticism of the nature of the regulations. He himself was not competent to deal with those criticisms, but it was a remarkable fact, and one which showed the tendency of modern legislation, that in the Dangerous Drugs Act, 1920, there should have been hardly any coercive provisions at all. That Act laid it down that regulations might be made, it was not definitely stated by whom, but there was a subsequent reference to the "Secretary of State," and the implication was that the regulations would be made by the Home Secretary. In the result the Home Office was left to make the whole of the regulations, infringement of which exposed the offender to the penalties prescribed by the Act. One would have thought that provision might have been made whereby the proposed regulations would be published in draft for criticism by the medical profession before they took final and effective shape. He contrasted some points in the regulations with what was proposed in the Dangerous Drugs and Poisons (Amendment) Bill, and urged the need for all such proposals to be placed before the medical profession. In the case of the bill the proposals could, of course, be examined and criticized before they became effective, but if he were a medical practitioner he would feel it a little alarming to be told that the Home Secretary had made certain regulations and that they would be published at a certain time, without knowing in advance what those regulations were, or without his profession as a whole having had the opportunity of seeing them and of submitting whatever was to be urged in respect of them: that might well be a genuine grievance. Those who had taken part in the proceedings in criminal courts would feel that the whole question was one of great importance. There the cases were usually brought forward on the charge of "being in possession." It was not a criminal offence to be an addict, but it was a criminal offence to be in possession of the drug, and this, of course, brought in the addict. In such cases the court would generally deal with the matter by using its powers to bind over the offender on certain terms or to put him under some kind of special probation, but there was a difficulty in committing any person compulsorily to any form of institution. That could only be done on the condition that the person concerned would be able to secure his release upon certain terms. When the case arose of a drug addict committing a crime, possibly owing to the deterioration which had taken place in his character, it could be dealt with more simply, and in some cases the most humane course was to treat it as ordinary crime, so as to secure that the offender was put in confinement in a prison for a reasonable period, during which, of course, he would not have access to the drug, while he would have competent medical treatment.

## British Medical Journal.

SATURDAY, MARCH 31ST, 1923.

### POST-GRADUATE EDUCATION IN LONDON.

THE present position with regard to facilities for post-graduate instruction in London is unsatisfactory; it seems, in fact, to have grown worse during the last eight or nine months. Before the war there had been established, mainly through the exertions of Sir William Osler and Dr. Hurst, a Post-Graduate Medical Association, which was to co-ordinate the scattered elements into an effective whole; later on the Fellowship of Medicine was formed, again with the help of Sir William Osler, to look after the social needs of medical visitors to London. The Fellowship of Medicine and the Post-Graduate Association were eventually combined into a single body, in which the identity of the latter was to a large extent lost.

When, in the winter of 1918-19, many medical officers of the Dominion and American armies, and of the British Territorial Force also, were being granted study leave the Fellowship of Medicine gallantly sprang into the breach and organized courses of which the medical officers mentioned showed their appreciation. The movement reached what the epidemiologists would call its "peak" in the very successful Special Clinical and Scientific Meeting of the British Medical Association held in London early in April, 1919.

Some time afterwards (in July, 1921) the Science Committee of the Association appointed a Post-Graduate Subcommittee. When it came to look into the matter it found that in Edinburgh and Glasgow post-graduate teaching had long been encouraged if not directly organized by the university. In Manchester, Birmingham, and Bristol the university medical faculty had taken the matter up, and Newcastle had a scheme of its own, countenanced by the medical faculty and worked through the North of England Branch. The Subcommittee therefore limited its investigation mainly to London. It saw that there were in London two post-graduate schools actually at work—the West London at Hammersmith and the North-East London at Tottenham—both, however, working independently of each other and of the university medical faculty. It learnt that the undergraduate schools, though in some instances organizing short courses for post-graduates and usually ready to welcome back an old student, were not willing to take graduates except under these special circumstances, and that in particular they did not cater for the foreigner. It knew also that many of the special hospitals were ready to receive a graduate, whether British or foreign, to attend their practice, and that some arranged special lectures and demonstrations. Finally, it had to consider the Fellowship of Medicine, which sought to be the central co-ordinating body, had arranged at various times a number of courses, and generally was anxious to give a helping hand to the medical stranger in London. The Subcommittee presented a report, upon consideration of which the opinion was reached that it was not necessary to establish a single post-graduate school and hospital, the view being, apparently, that the existing elements in London, if properly organized and combined, would provide what was wanted.

Of the Fellowship of Medicine and Post-Graduate

Association it may be said that it had kept the need for a better organization of post-graduate education in London before the University, the Ministry of Health, and the medical profession. It was mainly owing to its efforts that in January, 1921, the then Minister of Health (Dr. Addison) appointed a departmental committee "to investigate the needs of medical practitioners and other graduates for further education in medicine in London." Over this committee the Earl of Athlone, Chairman of the Middlesex Hospital, presided, and it included two other laymen well known for their interest in hospital affairs; for the rest it consisted of members of the staffs of the teaching schools of the University and of representatives of the Ministry of Health. The Committee was instructed to submit proposals for a practical scheme, and in its report issued in May, 1921, it made a series of recommendations which, in fact, contained a scheme. A school attached to a hospital centrally situated in London was to be devoted solely to post-graduate medical education, and was to be a school of the University of London, receiving substantial financial assistance from the Treasury through the University Grants Committee. It was recommended also that, in addition to the courses provided at the central school and at existing post-graduate schools, further facilities for post-graduate study should be made available at non-teaching hospitals and at Poor Law infirmaries. Finally, the Athlone Committee advised that an Institute of State Medicine should be established; this has been realized through the Rockefeller Foundation's gift of £400,000 for the erection and equipment of such an institute, and the promise of the Minister of Health that the Treasury will provide £25,000 a year for upkeep. The Fellowship of Medicine accepted the recommendations of the Committee, and expressed the hope that one of the existing undergraduate teaching hospitals would consent to be the general hospital of the school and cease to take undergraduates.

As after a year or more nothing had been done, and as in the meantime a new Minister of Health had come into office, a deputation was sent to him last July to enlist his sympathy and support. Sir George Makins, who headed the deputation, described the aims and hopes of the Fellowship of Medicine, and recalled the recommendations of the Athlone Committee. The Chairman of the Post-Graduate Subcommittee was able to state that the British Medical Association was taking an interest in the movement, but did not think that a post-graduate general hospital was essential to the establishment of a post-graduate school in London. The Minister (Sir Alfred Mond) was sympathetic, but non-committal; he, however, seemed disposed to hold to the departmental committee's recommendation that a central general hospital was a necessary part of any complete scheme.

The Vice-Chancellor of the University of London (Mr. H. J. Waring) has informed the Fellowship that the University feels strongly the need for a post-graduate medical school, to consist of a central general hospital with approved special hospitals associated with it, and having a Dean who should be provided with the necessary clerical staff and administrative offices, not necessarily at the central hospital, but possibly, as we gather, in the University building when it goes to Bloomsbury. That the University should have taken the matter up is an important step forward, more especially as the University Grants Committee can only make grants to university institutions; but the difficulties in the way are very great, and it is to be feared that a long delay is inevitable. The Fellowship had to frame a policy for the immediate future; it decided to carry on, and called a conference, which was attended by representatives of

twenty-seven non-undergraduate hospitals "doing, or willing to do, post-graduate teaching." They asked, and the Fellowship agreed, that they should be added to its General Council; in reply to the further demand that they should be added to the executive committee, the Fellowship decided to take steps to modify its constitution, which is undoubtedly very cumbrous. Subsequently the twenty-seven constituted themselves a permanent "Post-Graduate Committee," and a conference is to take place shortly after Easter between representatives of this new committee and of the Fellowship. We hope that in some way a scheme to meet the immediate needs will be devised of such a kind that it will eventually work in with the larger university scheme which is designed to place the metropolis of the empire in the leading position it ought to occupy.

### LORD BYRON'S LAMENESS.

It is close upon a hundred years since the sixth Lord Byron ended his tempestuous career at Missolonghi, yet books are still written and papers read in which attempts are made to clear up the "mysteries" of his career, though without, it must be confessed, much success. Dr. Jeaffreson, who attempted to depict the "real Lord Byron," dealt, as others have done, with the moral and intellectual character of the poet. It is a strange fact that the physical "real Lord Byron" is equally a mystery in one respect. It is well known that he was lame, and that he was ashamed of and tried to conceal his lameness; but beyond this we cannot go without plunging into a labyrinth of contradiction. Were both of his feet affected, or only one? If only one, which one? What was the cause and what the nature of the deformity? These are some of the questions to which no satisfactory answers can be given. Lord Byron can have had little real happiness in his life, but we feel sure that his vanity would have been pleasantly excited and his latter days rendered happier could he have felt sure that for ninety-nine years, and probably for much longer, his poetry, his peccadilloes, and his deformity would be discussed again and again by the curious.

Trelawny and others said that he suffered from club-foot, but this term was formerly used to include all forms of talipes, and little stress can be laid on such statements. One more attempt to clear up one of the uncertainties about Byron has been made by Dr. H. C. Cameron, whose address to the Royal Society of Medicine, excellent both in matter and manner of delivery, is reported upon another page. In attributing the lameness to infantile spastic paraplegia, the result of injuries of the cerebrum received at birth, he has brought forward a theory which, as far as we know, is new. Dr. Cameron certainly makes out a good case, ingeniously supported on such evidence as exists, but he cannot be said to have quite proved it.

Apart from the fact that the victims of Little's disease are generally distinctly below the average in intellectual power, and that Lord Byron's intellect was certainly above the average, we have only Trelawny's word for it that both feet were affected and that Byron could only run on the tips of his toes, and Trelawny is certainly a most untrustworthy witness. It might be argued that the case was one of mild cerebral monoplegia, affecting one lower extremity, for the overwhelming balance of evidence goes to show that only one foot was affected. Three witnesses say that it was the right and six that it was the left foot, but anyone who has had much to do with such matters will admit that it is extremely easy to make mistakes in speaking or writing about right and left.

The exhibits presented by Dr. Cameron are most interesting, but, as he said, the bootmaker's lasts show no evidence of deformity. It is to Mr. William White, Sub-librarian of Trinity College, Cambridge, that we owe the discovery of these relics of the poet; in a paper in the *Cambridge Graphic* of February 22nd, 1902, he stated that it was owing to his repeated urging that they were discovered in an outhouse in the Nottingham Museum. In this paper Mr. White puts on record additional evidence about the affected foot, obtained from a resident in Cambridge who claimed to have seen Byron daily when he was at the university, and who noticed nothing peculiar about the feet. Mr. White also referred to an engraving in the library, copied from a silhouette cut by Mrs. Leigh Hunt, which "represents the feet exactly as Swift speaks of them, and underneath the likeness are the following words: 'His lame foot (the left) but slightly altered his general appearance.'"

The two examples of the appliances worn by Byron on his right leg, which Mr. Murray lent to the lecturer, are of the very greatest interest. They are of soft leather, except the soles, which appear to be stiffened with metal plates, and, as will be seen from the photograph reproduced at page 564, each consists of a footpiece and an upper part extending to just below the knee, thickly padded as though to conceal atrophy of the calf. They conclusively prove that the right foot at any rate was affected, whatever may have been the condition of the left, and that the leg, and probably the foot also, was ill developed and much smaller than normal. The soles exactly correspond to the Nottingham last, and it would seem that they were made to be worn inside the boot or shoe, just as Hessian's and similar appliances are worn nowadays. The under surfaces of leather are not worn as they would be by contact with the ground. A striking feature in each of these two appliances is the wedge sole, by which the outer edge of the foot would have been raised a quarter or three-eighths of an inch more than the inner. Such soles are now used in cases of varus with the intention of throwing the foot outwards, but it is more likely that the maker of this appliance intended not to correct but merely to accommodate the over-pronated foot. If that were the case it would show that Byron suffered from valgus, which would be quite consistent with a long narrow foot, while varus is associated with a short broad foot such as could never have been fitted by these appliances or with boots made on the Nottingham last. If, as the lady quoted by Mr. White said, Byron rested his affected heel against the other foot, he must have had an everted and probably an over-pronated foot.

It must, we think, be considered as established that whatever the nature and cause of Byron's lameness, it did not result in any distortion of the foot that could not be concealed by ordinary shoes or boots. But that we have strong evidence that the condition was either congenital, or arose at the time of birth, we should have been disposed to attribute it to a mild attack of anterior poliomyelitis. In the circumstances the diagnosis must apparently be suspended between a congenital form of the rare atrophic variety and a post-natal valgus or calcaneo-valgus. This latter condition, unlike talipes varus, is peculiarly apt to improve spontaneously. May it not be the case, then, that the newborn baby had a deformity sufficiently obvious to lead the mother to consult John Hunter and others, but which afterwards diminished till it constituted only the slight disability known to Byron's friends in adult life?

The question can never be definitely settled, and even an exhumation of the bones now in the grave at Hucknall Torkard would not be likely to clear up the uncertainty. Despite this, Dr. Cameron is to be congratulated on his

ingenuity and research, resulting in a most interesting address which held the rapt attention of his audiences at the Social Evening of the Royal Society of Medicine.

### CRIMINAL RESPONSIBILITY.

A COMPARISON of the Memorandum of the British Medical Association and the Report of the Medico-Psychological Association prepared for submission to Lord Justice Atkin's Committee on the practice and procedure relating to criminal trials in which the plea of insanity is raised\* shows that, agreed as they are on several very important matters, there is an apparent discrepancy between them on what is perhaps the most important, the legal criteria of responsibility for crime. On careful reading of the two documents, however, this difference will be found to be more apparent than real, and to be due to the two committees not having consciously directed their minds to exactly the same point. Neither committee seems to have faced, or stated, quite clearly the conclusion to which its suggestions logically tend, and it is worth while trying, by a comparison of the two documents, to get this more definitely realized even though its practical application remain full of difficulty.

It is agreed that insanity is incapable of precise definition, but the question whether a person is or is not insane is a purely medical question. It may be very difficult to answer, and there may be differing medical opinions in this case as in others, but the whole matter is, we conceive, one of medical diagnosis. The questions as to whether an insane person should ever be punished by law for antisocial offences, and, if so, under what circumstances the penalty should be imposed, are not medical questions at all. They must be left to the legislature or to the courts. There are codes under which insanity, of and by itself, exempts the convicted prisoner from the prescribed penalty of his crime; but when this is not so the question of insanity is clearly not determinant. What the court has to determine in these cases is not the medical question of insanity, but the non-medical question of responsibility, whether the accused be insane or no. As a matter of fact, there are cases in which the court has in effect declared responsibility by inflicting the full penalty, even when there was medically no doubt as to insanity, and others in which the court has in effect declared irresponsibility by not inflicting the ordinary penalty when it would have been impossible for insanity to be medically certified.

This position is recognized in the first recommendation of the committee of the Medico-Psychological Association, which declares that "the responsibility of a prisoner should be left as a question of fact to be determined by the jury on the merits of the particular case." This being so, it might have been expected that the recommendation as to questions to be put to the jury would have been—(a) Did the prisoner commit the act alleged? (b) If he did, was he at the time responsible? leaving them to be answered solely on the evidence as to all the relevant facts "unhampered," as the body of the report says, "by any formula." The second recommendation of the committee, however, states that the second question should still be, "If he did, was he at the time insane?" and poses a third question to the jury in such form as in effect, so it seems to us, to establish a new criterion of responsibility—"that his crime was unrelated to his mental disorder."

Both committees are agreed that the M'Naghten rules should be abrogated, since the conception of unsoundness of mind implied in them is now obsolete. The British Medical Association Memorandum seems

to imply, without saying it in so many words, that the question "Is he insane?" must still be asked of the jury, and puts forward as a substitute for the M'Naghten rules another formula which differs from those rules by adding a further criterion of irresponsibility—namely, that the accused "is prevented either by defective mental power or by disease affecting the mind . . . from controlling his own conduct, unless the absence of the power of control is the direct and immediate consequence of his own default." This is, nevertheless, suggested somewhat hesitatingly, as one which "might be accepted by the medical profession as fair."

It is certainly imperative that the rules as they now stand should be abrogated or ignored; it does not appear to be established that the jury ought to be asked to declare insanity; it may fairly be argued that what they have to determine is responsibility. If the question of insanity is omitted, then the essential thing is to have a proper body of medical evidence regarding all relevant medical and psychological facts upon which the jury may come to a decision in each case. If the question of insanity is still to be put to the jury, and if in that event it is considered legitimate to ask the medical profession to help by advising as to criteria of responsibility, it will probably be found less difficult in most cases to determine that mental disorder prevents the prisoner from controlling his own conduct than that his crime was unrelated to his mental disorder at all.

The matter is very far from being settled, and we put forward these observations as an attempt to make the points at issue plain to readers who have not hitherto had occasion to give much thought to the subject. Lord Justice Atkin's Committee is now engaged in taking medical evidence, and we can only at present express the hope that the Committee's report will give a clear lead to the judicature.

### A HOSPITAL "MAINTENANCE" SYSTEM.

We published last week (p. 532) a notice of a financial reconstruction scheme for Scottish voluntary hospitals which Sir George Beatson, consulting surgeon to the Glasgow Western Infirmary, has recently issued in a pamphlet. He has given the name "maintenance system" to the scheme he enunciates. Briefly, it may be said that he divides the cost of hospitals into two parts—the maintenance of the hospital itself, and the maintenance of the patients. He proposes that the expenditure on the hospitals shall still be met by the contributions of the charitable public, but that the patients should pay, either personally or through benefit societies, for their food, drugs, and dressings. The sum so to be provided by or for the patients he estimates would, in Scotland, average about £1 a week. The interest now felt in the financial position of hospitals is so widespread that any suggestion from a hospital worker of such long and varied experience as Sir George Beatson is sure to command attention. There are some points in his scheme which may be felt to need further explanation. He states that voluntary hospitals no longer confine themselves to the field of work for which they were established—the care of the necessitous sick poor—but are meeting the needs of other sections of the community, such as artisans and members of the lower middle class. Sir George Beatson points out that voluntary hospitals have now to meet a much higher expenditure, especially on the surgical side, than in the past. What, then, it may be asked, is exactly meant by the term "necessitous poor"? The ordinary primary meaning of "necessitous" given in the *New English Dictionary* is "placed or living in a condition of necessity or poverty; having little or nothing to support oneself by; poor, needy; hard up." But this, in the circumstances, does not help us very much. Does ability to pay £1 a week under an insurance scheme requiring the payment of a few pence a week remove

\* See BRITISH MEDICAL JOURNAL, March 24th, 1923, pp. 518 and 523.

the individual from the ranks of the necessitous poor? Or, taking the other extreme, does inability to afford the cost of a surgical operation and a nursing home bring the patient within the class? Again, is a person logically a pauper to be included in the necessitous class? Sir George Beatson agrees that an "income limit" must be enforced by a voluntary hospital, but it is admittedly not easy to fix the measure of this limit. We understand Sir George Beatson to include in the maintenance of the hospital itself, besides buildings and rent and taxes, the expenditure on salaries and the running expenses in drugs, dressings, etc., of the out-door dispensary, as well as the cost of management. We gather that he would assign to the patients' side of the account the cost of wear and tear of equipment for serving food, and the surgical dressings. It will, we suspect, be difficult to make a sharp distinction between the two headings of expenditure for maintenance of hospitals and expenditure on maintenance of patients. Sir George Beatson's scheme must be considered in its relation to the present hospital policy of the British Medical Association. He says that a "definite advantage of the maintenance system is that under it there will be no grounds for medical men claiming remuneration for the services they render, because the hospitals will be receiving no payment for treatment." The Association proposes that in the event of patients paying in part or in whole the hospital maintenance fees, either individually or by some contributory method, or with the addition of rate or State aid, or a combination of any two or more of these methods, a percentage of all such payments should be passed into the staff fund. At the Annual Representative Meeting last year a resolution was adopted affirming that where such payments are in part made by rate aid or State aid, or in other cases are of an amount exceeding the cost of hospital maintenance and accommodation, such charges should be considered to include payment towards maintenance and treatment, and a percentage of all such payments should be passed into a fund to be at the disposal of the honorary medical staff. This resolution, along with certain others, was referred to the Council, which, at its meeting on October 25th, 1922, adopted a memorandum which has been circulated to the Divisions and was published in the SUPPLEMENT on November 18th (p. 186). Sir George Beatson's scheme is not in accord with that contained in the memorandum, but the views he expresses are ingenious and stimulating and therefore worthy of study.

#### A NEW THEORY OF MINERS' NYSTAGMUS.

At a meeting last week of the South Wales Institute of Engineers a paper was read by Dr. Frederick Robson in which he presented some observations upon the prevalence of miners' nystagmus in the South Wales coalfields. He gave a general survey of these coalfields to explain the influence of the metamorphoses of coal, with special reference to the production of volatile bodies and their distribution horizontally and perpendicularly (by pits). There is a considerable difference in the percentages of volatile content of coals in the adjacent areas, and Dr. Robson states that it is in direct relation with the incidence of nystagmus amongst the miners. Monmouthshire, with a volatile content of the coal of 29.50 per cent., gave 4.56 per cent. of nystagmus amongst men employed below ground; Glamorganshire East, with 29.50, showed 2.22 per cent. of nystagmus; Glamorganshire West, with 25.50 per cent., showed 1.90 per cent. of nystagmus; and Carmarthen, with 11.86 per cent., showed 1.15 per cent. of nystagmus. The statistics, he maintains, appear to show "a partial parallel analogy in the incidence of nystagmus to percentage of volatile matter, as disclosed by analysis of the various seams passing from east to west and from south to north." When these seams are examined in these directions it is found that the coal is progressively less bituminized. The coals are, however, not homogeneous, so that difficulties arise in establishing the exact relation of the statistics. It is, however, a striking

observation that in Monmouthshire, where the percentage of volatile content is nearly twice that in Glamorganshire (whole county), the nystagmus is more than double that found in the less volatile coal fields. Dr. Illingworth, who has been associated with Dr. Robson in this work, states that coal of a bituminous kind gives rise to dust at the face by "geological" attrition, which oxidizes readily at pit temperature, with the formation of carbon monoxide gas. The inference that a gas or gases is the generic cause of nystagmus is held to be supported by strong presumptive evidence. So far as is known the blood content of miners working in the most gassy mines has not been investigated, and it is suggested that this should be done. Negative evidence against the usual theory of defective lighting as the cause of nystagmus is contained in a series of observations made in the Rhondda Valley over a series of years (1909 to 1923). There have been two peaks of high incidence of nystagmus, the one in 1914 and the other in 1920. During this period there has been a steady increase in the use of electric lamps; they were introduced in 1913; last year 60,000 lamps were in use, and there has been an equivalent reduction in the use of locked oil lamps. The number of men increased in each of the two years of the peaks of incidence of the nystagmus, but the men's working time has been reduced, and wages have increased, both factors which should reduce the risks of the disease if the actual coal cutting were the primary cause. Against this there has been an increase of compensation, from £1 to 25 shillings a week in 1917, and to 35 shillings in 1920; this may have conduced to the more general reporting of cases. The author concludes that "it is obvious that coal getting *per se* is not the main cause of nystagmus." Further, he states that it takes twenty years underground in the hard coal areas to produce a nystagmic patient, whereas in the soft coal or bituminous pits, as in Monmouthshire, nystagmus may be contracted in two years. Dr. Robson is collaborating with Professor George Knox and Dr. S. Roy Illingworth, of the Treforest School of Mines, in an examination of coal dusts and mine gases in selected pits, as far as they may relate to the origin of nystagmus. It is proposed to correlate their results with Dr. Robson's in order to prove or disprove his hypothesis that coals give rise to different percentages of nystagmus in some ratio to their volatile content, the volatile content being an index of the kind of coal giving rise to the disorder. The results of this combined inquiry will be awaited with interest.

#### THE PROGRESS OF CREMATION.

It was reported at the annual meeting of the Cremation Society of England, held on March 21st, that the number of cremations in Great Britain in 1922 was 2,009, an increase of 87 on the figure for the previous year, although slightly below the highest total for a year, which was reached in 1919. The total number of cremations since the first in 1885 is 27,429, and of these nearly one-half have taken place at Golders Green. It was only to be expected that attention should be drawn in support of cremation propaganda to the recent exploration of the tomb of Tut-ankh-Amen; it served to point the moral that the disturbance of the dead for purposes less scientific and more basely utilitarian than those of the archaeologist is taking place all the time, with the requisitioning of burying grounds for street widenings or railway extensions or other improvements. The urban cemetery is by no means the place of uninvaded sanctity and rest which is pictured in Gray's "Elegy," and such disturbance is inevitable, for, as Sir John Simon remarked sixty years ago, every dead body receives its accommodation at the expense of the living and to their detriment. To the objection to cremation that it would sometimes enable crime to be successfully concealed, the Council in the annual report points out that the several exhumations lately necessary might have been prevented had the same precautions of strict inquiry into the cause of death been taken before burial as are taken in the case of a body which it is proposed to cremate. It is the lax burial system—not the practice of cremation—which offers facilities for

concealment, and the probability is that a larger number of crimes escape detection on account of this laxity than are brought to light by exhuming the body. Sir Malcolm Morris presided over the annual meeting, when the Duke of Bedford was re-elected President, and certain formal business was transacted consequent upon the recent reconstitution and incorporation of the Society. Occasion was taken to mention the progress of cremation in other countries, especially in Sweden, where a propagandist effort is being made by the Swedish Cremation Union during the Jubilee Exhibition at Gothenburg in the coming summer. The head of the committee in charge of the work is Dr. Veener von Heidenstam, Fellow of the Royal Swedish Academy, and the necessary funds for organizing the effort are being supplied by the Swedish Government and the municipalities of Stockholm and other cities, as well as by organizations specially interested in the cause of cremation.

#### INDUSTRIAL PSYCHOLOGY.

THE second anniversary meeting of the National Institute of Industrial Psychology was held last week in the rooms of the Royal Society. The Earl of Balfour, in moving a resolution calling for support for the Institute, said that in spite of the great services rendered by British scientists, the value of the work which science could do for society had been underrated in this country. This was due partly to the rightful zest for pure science which animated the scientific mind; if men of science were not interested in the abstract and non-utilitarian aspects of their work science itself would languish and be near its doom. But science could intervene to more purpose in industry, greatly to the advantage of the State. One means of intervention was through the physical and chemical sciences, whereby discoveries were turned into inventions. Even in this obvious application a great deal of apathy still existed which made him anxious for the future of British industry. Another task of science in industry was to protect the workman from the diseases and accidents incidental to his calling. A third was industrial psychology, and here, whatever might be said of other applications of science to industrial work, there could be no collision between employer and worker. The primary object of industrial psychology was to make the labours of the wage-earner easier, smoother, more pleasurable, and more productive. Intelligent investigation and experiment could do much to elicit the true laws which ought to govern physical effort. What Bacon described as the object of science—"the relief of man's estate"—could not be pursued on safer, sounder, and less controversial lines than those which the Institute had adopted. Sir Charles Sherrington, P.R.S., also spoke on the great variety of problems which had been already undertaken by the Institute, such as the study of miners' movements in coal getting, rest pauses in catering work, and the simplification of packing in the factory. Forty years ago psychology was modestly invading the universities as a laboratory subject, but for some years it had hardly a laboratory to call its own. It occupied itself at first in exact time measurements of repetition processes, and went on to study the factors of attention, memorization, mental fatigue, interest, monotony, anxiety, and other emotional states. Every modern process of industry involved perhaps thousands of operations, each one depending on a mental situation, with favourable or unfavourable elements. In the modifications of these processes, as well as in vocational selection and the study of the predilections and disabilities of individuals, industrial psychology was proving its worth. Other speakers were Sir Lynden Macassey, K.C., Mr. Arthur Pugh, of the Iron and Steel Trades Federation, and Dr. C. S. Myers, the Director of the Institute. Dr. Myers said that the experience of the Institute was that deficient output was due less to intentional restriction than to bodily and mental conflicts with environment. The investigators from the Institute had found labour intensely interested in the possibilities of affording better guidance, based on proper tests, to those deciding on the operations for which they were best fitted. It was the employer, who asked for

immediate results, or for a guarantee of an extra percentage of profit, who needed educating in industrial psychology. The Institute had undertaken some investigations on illumination in a Lancashire coal-mine. The result of substituting diffused for undiffused light at the coal face had been an appreciable increase of output of coal, and the new lamps giving greater brightness of illumination could not be supplied fast enough to the colliers, who stated that the lamps had made the work easier and involved far less strain on the eyesight. Another piece of work had been the study of breakages in a tea-shop. Here improvements in methods of ventilation, devices for screening the workers from excessive heat, and the reduction of danger points of irritation and fatigue had resulted in a diminution of 53 per cent. in the number of breakages.

#### RADIOLOGY IN PRACTICE.

MR. C. THURSTAN HOLLAND, D.L., Ch.M., has been appointed honorary consulting radiologist to the Royal Infirmary, Liverpool. This recognition of his distinction as a radiologist will, we believe, give great pleasure to his brother radiologists and to all members of the profession who know the excellence of his work. He was one of the first to take up the study of the practical application of x rays in diagnosis and treatment. He pursued it in a true scientific spirit, and on this account his influence on the development of medical radiology has been, and we hope will long continue to be, very great. He has steadfastly maintained the thesis that radiology for diagnosis or treatment should be conducted by members of the medical profession themselves, and that it is the duty of the radiologist not only to take good plates but to interpret them, the radiologist having his part to play, and a very important one it is, in the diagnosis of any case in which his co-operation is invited. Mr. Thurstan Holland, by his character no less than by his skill, enjoys to the full the confidence of all members of the profession who are associated with him in clinical work, and that he commands the respect of the members of his own specialty is shown among many other evidences by the fact that he has been selected to give the Silvanus Thompson lecture of the Roentgen Society on May 1st.

THE King and Queen have promised to lay the foundation stone of the new Rockefeller building of University College on some day towards the end of May. On the same occasion they will open the anatomy buildings of University College, which are nearing completion.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Dangerous Drugs and Poisons (Amendment) Bill.

*Amendments in Standing Committee.*

THE Dangerous Drugs and Poisons (Amendment) Bill was taken in Standing Committee B in the Commons on March 26th, Mr. Arthur Ponsonby presiding.

The proceedings were very brief, occupying less than half an hour. All the amendments on the notice paper, with the exception of two (of no importance and not proceeded with), were in the name of the Home Secretary and they were all agreed to. It was understood that this was the result of arrangements between Mr. Bridgeman, on behalf of the Government, and the medical group, university members, and the British Medical Association. The full text of the bill was given in the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of February 24th (p. 59), from which it will be seen how the amendments apply. In Clause 2, at the end of the subsection dealing with fines and their disposal, the following amendment was inserted:

(2a) No proceedings for an indictable offence against this Act shall in England or Wales be instituted except by or with the consent of the Attorney-General or by the Director of Public Prosecutions, and no person shall, on conviction for any offence of contravening or failing to comply with any regulation under this Act relating to the keeping of books or the issuing or dispensing of prescriptions containing drugs to which this Act applies, be sentenced to imprisonment without the option of a fine or to pay a fine exceeding fifty pounds, if the court dealing with the case is satisfied that the offence was

## England and Wales.

### POST-GRADUATE WORK IN BIRMINGHAM.

The Clinical Board of the University of Birmingham has arranged a course of post-graduate demonstrations to be given at the General Hospital, Birmingham, on Tuesdays, from 3.30 to 5 p.m., during April, May, and June. The board believes that such practical demonstrations will prove of great value and will be appreciated by members of the profession residing within reach of Birmingham. The course, which will be given by members of the medical and surgical staffs, will include demonstrations on skin disorders, nervous disorders, surgery, diseases of the heart and of the nose and throat, on chronic arthritis and its treatment, on the methods of investigating diseases of the stomach, on diabetes, on nephritis, and on common deformities of the feet. An advertisement appears in another place, but we may say that the first demonstration will be given on April 17th. The fee for the course is one guinea, and full particulars can be obtained from the clerk to the Clinical Board, the University, Edmund Street, Birmingham.

### "ASYLUM" OR "MENTAL HOSPITAL."

A question of nomenclature is raised by the visiting committee of the City of London Mental Hospital, Stone, near Dartford, in its annual report for 1922. For many years past, it says, to meet the objections raised by the friends of patients to the description of that institution as the "City of London Asylum" the words "City of London Mental Hospital" have been substituted. The committee is, however, advised that for all legal and official purposes it is bound by the description "asylum" laid down in the Lunacy Acts. This inevitably leads to inconvenience and confusion, and the committee recommends that steps should be taken by the City Corporation to get a clause inserted in the next General Powers Bill authorizing the use of the gentler expression in describing the institution for all purposes. For some time there has been a feeling throughout the country that the description "asylum" should be dropped in connexion with institutions for the treatment of the mentally afflicted.

## Scotland.

### POST-GRADUATE TEACHING IN GLASGOW.

Under the auspices of the Glasgow Post Graduate Medical Association arrangements have been made for the provision of post-graduate teaching for medical practitioners from May until October of this year. The teaching facilities are of two forms—clinical courses and clinical assistantships—and are designed to meet the needs of practitioners who wish to refresh their knowledge of one or more subjects, and at the same time to make provision for those who wish to spend a few months in the more intensive study of one particular subject. The courses are held in the different infirmaries and special hospitals of Glasgow, and the subjects include clinical medicine, clinical surgery, clinical obstetrics, clinical gynaecology, diseases of children, ophthalmology, diseases of the ear, throat, and nose, dermatology, urology, orthopaedics, venereal diseases, and several others. Most of the clinical courses extend over one or two months, on one, two, or (in a few cases) three days of each week; in ophthalmology an intensive course will be held daily throughout September. As regards clinical assistantships arrangements have been made whereby a limited number of practitioners can become attached to wards or out-patient departments under the direct supervision of the physician or surgeon in charge, and they will be able to take advantage of the facilities for intimate study of the cases, carrying out detailed investigations as directed. These clinical assistantships are, in most instances, available not only during the coming summer, but throughout the whole year; they provide exceptional opportunities for those who are able to devote the necessary time to the work—either the whole or part of the day—and are intended to appeal especially to young graduates who contemplate practising in some special subject, and to practitioners from overseas who wish to become acquainted with the most modern methods of diagnosis and treatment. Further information may be obtained on application to the secretary, Glasgow Post-Graduate Medical Association, the University, Glasgow.

## Ireland.

### DUBLIN INFANT AID SOCIETY.

The report presented to the annual meeting of the Infant Aid Society, at which Sir William Wheeler, President of the Royal College of Surgeons in Ireland, was in the chair, stated that during 1922 the amount of relief distributed was 12,767 gallons of free milk, at a cost of £1,190 7s. 5d.; 6,758 gallons of milk sold at a reduced price, £616 4s.; 4,629 free dinners, £51 13s. 7d.; 369 lb. free dried milk, £29 3s. 6d.; and 435 lb. dried milk sold at a reduced price, £34 7s. 9d. There were 47 bags of coal and 804 garments also distributed. All this relief was distributed on the advice of voluntary visitors of the society, who undertook to visit and care for a year the destitute mothers and infants recommended by the nurse of the district. The total number of visits paid by these voluntary visitors during the year was 9,996, an increase of 3,553 on the previous year.

The report expressed appreciation of the good work done by the five nurses and health visitors of the society, who with the eight nurses of the Central Babies' Club Committee, visited all the poor families within the city. The total number of visits paid by the five nurses and health visitors was 31,233, an increase of 1,178 on the previous year. The workers of the society paid 41,299 visits, a total increase of 4,731. The visitors had very often to act as counsellors and friends of the mothers and fathers. There was great poverty in the city, and unemployment seemed to be as great as it was last year. The times were abnormal, and the series of shootings and explosions which had occurred in the city for the past eight months or so must have affected the health of the mothers and their babies. The treatment of delicate babies and expectant mothers formed an essential part in the work of the society. During the year 363 infants had received hospital treatment through the society, which was greatly assisted by the help it received from the National Maternity Hospital, Holles Street, St. Ultan's Hospital, the Children's Hospital, Temple Street, the Children's Hospital, Harcourt Street, the Orthopaedic Hospital, Richmond Hospital, Linden and Stillorgan Convalescent Homes, and the Children's Holiday Home, Cheeverstown. The report also expressed indebtedness to the Sick and Indigent Roomkeepers' Society, the Society of St. Vincent de Paul, the Dublin Corporation, the Albert College Farm, Glasnevin, and the Cowkeepers' Association, for supplying milk at a reduced price; the Local Government Board, the Irish White Cross, the Ada Lewis Distress Fund, the Rev. Mother, St. Vincent's Hospital, the Dominican Convents, Eccles Street and Muckross Park, the Provincial, All Hallows College, for free milk, and to many other helpers and subscribers. The adoption of the report was moved by Mr. McArdle, who said that the strength of a nation lay with the children. The chairman, in putting the motion, which was carried unanimously, said that their storm-tossed vessel in Ireland would have to be repaired by the children growing up. In all questions of health, and in all questions of the support of hospitals, Ireland was far behind other countries in Europe and behind the United States. In the areas in Dublin where the Infant Aid Society was working the mortality amongst children had been considerably reduced. Dr. Reginald White, the President of the society, to whose energy a great deal of its success was due, had reminded him that the normal mortality in Dublin amongst infant children was 160 per 1,000—an appalling state of affairs—but that in a district where the Infant Aid Society was active it fell to 110—a very considerable reduction.

### TUBERCULOSIS IN CO. ARMAGH.

In his annual report Dr. Robinson, tuberculosis officer for co. Armagh, states that during the past year twenty-one new cases received dispensary treatment and nine sanatorium treatment. With reference to the inquiry of the Ministry of Labour as to the relative value of the various forms of treatment he states that he had no doubt that if the patient came under observation in the early stage—which, unfortunately, did not often happen—and was willing to submit to medical advice, residence in the sanatorium was the best, for not only would the disease be arrested but he would be taught much that would be of service to him when he returned home. In 1922 the number of deaths was 26, as against 248 in 1913, the first year of the working of the scheme. Though the number of deaths from pulmonary tuberculosis was smaller

he thought there was very little doubt that a large number of deaths from "other forms" was due to milk infection, and showed the necessity for a thorough testing and inspection of the milk supply. The number of deaths from the pulmonary type could also be reduced if a comprehensive building scheme were adopted. Larger and better houses were required. In the long run a healthy A1 population was of more benefit to the State than a B2 population. It was not unusual for him to find a patient suffering from advanced pulmonary tuberculosis occupying the same bed with two or three others. Dr. Robinson remarks, in conclusion, that the treatment of tuberculosis is not so hopeless as some imagine. Several patients who were under his care years ago are at present enjoying good health and at their ordinary work.

### THE CONGRESS OF MEDICINE IN VIENNA.

SIR,—The Congress for Internal Medicine to be held in Vienna from April 9th to 12th is not in the true sense of the word an international one, but the authorities have always welcomed the participation of foreigners on an equal basis. Personally I believe that true international congresses are impossible at present, but these local meetings, where outsiders are welcomed, form the best method, in my opinion, for the resumption of international relations. Vienna is peculiarly adapted at the present moment for this purpose, because Professor Wenckebach, who came from Holland to take up this important position in Vienna, is well known to many English physicians and scientists.

The notice has been issued too late for most of us to be able to attend, but it is possible that this may catch the eye of some younger men who would be free to undertake the journey.—I am, etc.,

London, W., March 20th.

HENRY HEAD.

\*\*\* The fact that the congress was to be held was mentioned in our columns of March 17th (p. 491). The Austrian Legation (18, Belgrave Square, S.W.1) now states that visitors from the United Kingdom will be particularly welcome and everything will be done to facilitate their journey to and stay in Austria, that the cost of the journey has been specially reduced, and that full information can be obtained on application to the Legation.

### SKIN RASHES FROM DYED FUR.

SIR,—Apropos of Dr. Semon's note in the JOURNAL of March 17th (p. 467) I had, some considerable time ago, corroboration of his diagnosis. I reported to Messrs. Nobel's Explosives Co. on a possible claim for compensation, in the case of a gelatin worker who had been certified by her medical attendant to be suffering from "dermatitis due to chemicals."

On examination the worker did not show actual dermatitis, but a blotchy erythema of neck and chin, with urticarial swelling of eyelids. She was not exposed in her occupation to any nitro body that would give rise to such a condition, and her hands, which were chiefly involved in her work, were free from any inflammatory condition. Inquiry as to hair washes, face pomades, powders for complexion, photographic material, petrol and paraffin, and soaps yielded negative results. A feature was that on a Saturday she had been certified by her medical attendant as having recovered, and after two hours' work on the Monday following the face was so inflamed that the ambulance attendant at the factory sent her home.

The food, occupation, and clothing of the Sunday were considered. A mustard-coloured, cheap felt hat was inspected, and showed at the curled-up brim behind a dark smudge. The worker explained that this came from a new fur she had bought. The fur was then inspected. By wetting a prescription form and rubbing same on surface of fur a brown smudge was obtained. The lining was unpicked and a smudge was obtained by rubbing a moistened paper on the pelt. The distribution, the freedom of the hands from eruption, and the fact that the appearance of the eruption was not suggestive of nitro-body rash, were sufficient to warrant a report that the condition was due to the fur wrap.

The worker returned to work and ceased wearing the fur and had no further trouble. The reappearance of the eruption on the Monday is due to the fact that, whatever the dye is, it is one which is more irritant in presence of moisture.

The urticarial condition favours the impression that the dye is an arsenical compound.—I am, etc.,

HARRY M. ROBERTS.

Stevenston, Ayrshire, March 17th.

### HAEMOCLASIC CRISIS AS A TEST OF HEPATIC INSUFFICIENCY.

SIR,—Dr. Langdon Brown, in his most interesting lecture in the BRITISH MEDICAL JOURNAL of March 17th (p. 461), on laboratory tests in disease of liver and pancreas, quotes the above test as a sign of hepatic insufficiency. The main points of the test are the post-prandial leucopenia, fall in blood pressure, alteration in viscosity of blood, and the explanation was the entering into the systemic circulation of improperly metabolized protein, said to be due to insufficiency of the liver.

Müller, in an article entitled "New glimpses into the regulation of vascular tonus" in the *Jahreskurse für Ärztliche Fortbildung* (January, 1923), gives an entirely different interpretation of this reaction, showing that it is evidence of a vagotonic state, and that identically similar reactions can be obtained from the intracutaneous injections of various non-specific substances. The article seems to me to be very convincing, being supported by authoritative references and experiments all through. I should like to know which of the two views is the correct one.—I am, etc.,

Darlington, March 19th.

R. CHALMERS.

### HOSPITAL POLICY.

SIR,—In the JOURNAL of March 24th (p. 533) Dr. Fothergill states that if the staff of a voluntary hospital is paid for its services it follows that the members of the board of management must also be paid; this is an argument that has frequently been used, but for which I can see no foundation. Members of the boards of management of many institutions where the staff is paid, such as asylums, sanatoriums, and infectious diseases hospitals, do their work voluntarily as part of their public duties; indeed, I know of no such institution where they are paid. Moreover, the position of a member of a board of management is entirely different from that of a member of the medical staff; the former is not giving the services of his particular profession or business by which he makes his living, as is the latter; auditors, solicitors, architects, and other professional men whose special services are required by the hospitals are for the most part paid.—I am, etc.,

Bradford-on-Avon, March 24th.

CHAS. E. S. FLEMING.

SIR,—The correspondence in the JOURNAL on hospital policy is of much interest, though one could wish that there were a greater variety of writers so that a wider scope might be given to the discussion. Up till now it appears that there has been chiefly the reiteration of opinions by a few correspondents.

One point I would like to make. In letters in the issues for March 17th and 24th there have appeared statements to the effect that the policy of the Association will bring about the aggregation of all or nearly all the consulting and specialist work for contributory schemes within the voluntary hospitals. Such a statement as this shows that the writers of the letters have not refreshed their memories of the resolutions passed at the Annual Representative Meeting, 1922. The fear which they have in their minds is expressly guarded against in the Association policy. At the meeting of the Marylebone Division<sup>1</sup> when the application of Dr. Gordon Dill's contributory scheme to London was under discussion I pointed out that a serious danger, for London at any rate, arose from the risk that consultations and specialist services for the patients accepted under such schemes might tend to be limited to hospital staffs, and that measures must be taken to prevent this. Later the Hospitals Committee, the Council, a general conference of hospital staffs, and finally the Annual Representative Meeting, accepted two resolutions which are designed to prevent such a happening. They are as follows:

Para. 28. Where arrangements for consultations or specialist services for tariff patients are made under some contributory scheme or otherwise, such arrangements should provide that the services shall be given so far as is possible and consistent with the best interests of the patients by the private practitioner at his consulting rooms or at the patient's own home and not at the out-patient department of the voluntary hospital.

Para. 31. Full opportunity should be given to private practitioners who possess the necessary qualifications and experience to participate in the work of voluntary hospitals, and for that purpose—

(a) The age limit or tenure of office of members of the honorary medical staffs of voluntary hospitals should, where necessary, be so modified as to allow more and younger practitioners to obtain responsible hospital experience.

<sup>1</sup> SUPPLEMENT, BRITISH MEDICAL JOURNAL, November 25th, 1921, p. 121.

frequent contact with Sir William. At this period he was more concerned with the organization of work and with broad generalizations, yet I do not think he ever showed himself to greater advantage than in his dealings with these cases at this time; at this time, also, he was suffering severely from his own personal bereavements. After the war I knew him as a colleague on the staff of the Royal Infirmary, and another side of his complex character dominated. Questions of hospital policy and details of medical administration received the same attention as in earlier days had been expended upon the cutaneous distribution of spinal segments, or the clinical aspects of the cervical rib, and were left again in the same state of completeness.

It became more and more obvious during these latter years that Sir William's interests were turning in the direction of medical politics, and his untimely death has been a blow to all of us, his students and his colleagues, who felt that he might one day have filled with distinction the presidential chair of the Royal College of Surgeons. Sir William was, I should say, by nature a very nervous and a very self-conscious man, and his aloofness and somewhat terrifying personality were of the nature of over-compensation in the opposite direction. Such men are not always sufficient for themselves, but it is among them, often enough, that the best workers are found.

A special service was held on March 21st at the Manchester Cathedral, which was filled by a large congregation, medical and lay women as well as men, who attended to pay their last respects to a friend and fellow worker or trusted adviser. The Royal College of Surgeons of England was represented by Sir Berkeley Moynihan and Mr. Thelwall Thomas; the University of Manchester by Professors H. B. Dixon, J. Shaw Dunn, J. S. B. Stopford, T. F. Tout, and R. B. Wild; the University of Liverpool by its vice-chancellor, Dr. Adams; the Army Medical Service by Colonel F. H. Westmacott; and the Manchester Medical Society by Sir William Milligan. The Board of Management of the Manchester Royal Infirmary, the Medico-Ethical Association, the old Owensian Society, and the St. Andrews Society of Manchester were also represented. Very many members of the staff of the Manchester Royal Infirmary were present, and also representatives of the nurses, as well as many personal friends in the profession. The interment took place afterwards at the Manchester Southern Cemetery.

A slight correction has to be made in the notice published last week. Sir William Thorburn had three sons: one died in 1910, one died in China in June, 1914, and Lieutenant F. E. Thorburn was killed in Gallipoli.

Dr. J. LLEWELLYN REES of Pontardawe died on March 4th, aged 58. He was the son of the late Rev. William Rees, vicar of Llanboidy, was educated at Llandovery and at the London Hospital Medical College, and took the diplomas of M.R.C.S. and L.R.C.P. Lond. in 1883. After serving as clinical assistant to out-patients and in the skin department of the London Hospital, medical officer to the Provident Dispensary, Bethnal Green, and as senior resident surgeon to the Royal Sea-Bathing Hospital, Margate, he succeeded Dr. Grice Jones in practice at Pontardawe some twenty-three years ago. He was medical officer to the Pontardawe and District Fever Hospital at Gellynudd since its opening. Dr. Rees, who was a member of the Swansea Division of the British Medical Association, was a keen sportsman, and well known as a Rugby footballer in his hospital days. He is survived by two sons and two daughters.

We regret to announce the death of Dr. H. W. McCauley HAYES of Madras. He was educated at the University of Edinburgh, took the Scottish triple qualification in 1887, and became M.R.C.P. Edin. the following year. He also took the Diploma in Public Health of the University of Liverpool in 1909, and four years later the Diploma in Tropical Medicine at the University of London. After serving as surgeon to the Victoria Hospital, Swindon, he became medical officer of the South Indian Railway, where he gained the respect of all with whom he came in contact, and was particularly popular in the social life of Trichinopoly, where the headquarters of the railway are situated. Owing to the depletion of South India of its I.M.S. officers in consequence of the war, Dr. Hayes's services were requisitioned by the Government, and he was appointed to act as superintendent of the Madras Lunatic Asylum, in the work of which institution he showed great interest, especially in regard to the welfare of the inmates. Dr. Hayes was honorary treasurer of the South

Indian and Madras Branch of the British Medical Association, and was lieutenant-colonel in the Indian Defence Force Medical Department.

The death of Sir ERNEST CLARKE calls for at least passing notice here. He was born in 1856, and at an early age became a clerk in the Medical Department of the Local Government Board. He was a man of unusual ability and energy, possessed by the ambition commonly associated with these qualities, and that department then afforded little scope; he left it in 1881 for the Stock Exchange clearing house, and afterwards, in 1887, became secretary of the Royal Agricultural Society. He was the first incumbent of the office of Lecturer on Agricultural History at Cambridge (1896-99). Owing to a mistaken policy for which Clarke was in part held responsible, he retired from the service of the Royal Agricultural Society in 1905 and had not since held any public appointment. During the eighties he was an assiduous and valued contributor to this JOURNAL. It is difficult, even for those who lived through it, to put the mind back to the state of things in public health at that time. The awakening had begun, and the British Medical Association, through its old Public Health Committee, and its JOURNAL, then edited by Ernest Hart, with Clarke as one of his most trusted advisers, did much to stimulate public opinion to demand better things. A great deal of the time and energy of medical men and of the space of this JOURNAL were occupied in arguing for propositions which are now commonplace; big epidemics of typhoid fever were still common, tuberculosis was popularly regarded as a hereditary disease by which certain families were inevitably affected, the death rate was high, and the infant death rate still higher. Clarke whole-heartedly believed that these things could be mended, and worked ardently with the limited means open to him to end them. It was a characteristic example of English slowness to entertain new principles that means were not found to keep him in the central public health service. It was not the fault of the sorely tried medical department of that day.

## Medical News.

THE Medical Research Council issued, on March 23th, a report entitled the *Schick Test, Diphtheria and Scarlet Fever* (H.M. Stationery Office, 1s. net), by Surgeon Commander Sheldon F. Dudley, R.N. The report is founded on a study of the incidence of diphtheria and scarlet fever in the Royal Naval School at Greenwich. The author has been able to differentiate between the invisible "epidemics of carriers" and "epidemics of immunization" on the one hand, and the visible epidemics of disease on the other. He concludes that the *Schick test* is a reliable method for ascertaining who are immune to diphtheria, and that the percentage of doubtful reactions can be reduced to two or three. We propose to refer more fully to this valuable report in our next issue.

THE arrangements of the Royal Institution for lectures after Easter include a course of four lectures by Sir Arthur Keith on the machinery of human evolution; the first of this course will be given on April 10th at 3 p.m. Two lectures, of which the first will be given on May 31st, will be delivered by Sir William M. Bayliss, on the nature of enzyme action; and among the Saturday afternoon lectures are two by Dr. Leonard Williams on the physical and physiological foundations of character, of which the first will be given on April 28th.

THE memorandum on the Dangerous Drugs Regulations prepared by the Home Secretary in conjunction with the Minister of Health and the Scottish Board of Health, which was reproduced in the JOURNAL on January 13th, 1923 (p. 63), has now been printed and put on sale. Copies may be obtained, price 2d. each, through any bookseller or direct from the Stationery Office at Imperial House, Kingsway, London, W.C.2, or the dépôts at Edinburgh, Manchester, and Cardiff.

ESSAYS for the Gifford Edmunds prize in ophthalmology awarded every two years for the best compilation on a subject dealing with ophthalmology and including original work, must be sent by December 31st, 1924; the subject selected for the next award is irido-cyclitis. Particulars of the prize can be obtained on application to the Secretary, Royal London Ophthalmic Hospital, City Road, E.C.1.

MR. STEPHEN PAGET has contributed an introduction to a book, *Medical Practice in Africa and the East*, which is about to be published by the Student Christian Movement. The book consists of a series of open letters on professional subjects from men and women doctors with many years' experience in India, China, or Africa.

NOTE.—It is against the rules of the Post Office to address either in initials or numbers.

## A British Medical Association Lecture

ON

## CONGENITAL HYPERTROPHY OF THE PYLORUS.\*

BY

GEORGE F. STILL, M.A., M.D.CANTAB., F.R.C.P.LOND.,

PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET; PROFESSOR OF DISEASES OF CHILDREN, KING'S COLLEGE HOSPITAL.

So much has been written in the last few years on congenital hypertrophy of the pylorus that one is almost inclined to apologize for broaching the subject again. It seems, however, worth while to sum up the results of one's experience when that experience is perhaps unusually large and extends far enough back to give some sort of perspective of progress in respect of the particular disorder, especially as to treatment.

In the past twenty-four years I have had under my own observation, either in my wards at hospital or in private practice, 248 cases of congenital hypertrophy of the pylorus. These figures must not be taken as indicating that the condition is of frequent occurrence. On the contrary, it is so uncommon that many practitioners of large experience tell me they have never seen a case. In the past, no doubt, congenital hypertrophy of the pylorus must often have run its course unrecognized, labelled perhaps "marasmus" or "chronic gastric catarrh"; but time has changed all this, and whereas in former years a case seen in consultation had almost invariably been undiagnosed, now the condition has almost always been suspected, if not recognized.

In outline the picture is now very generally known, thanks largely to the writings of Dr. John Thomson of Edinburgh. An infant three or four weeks old who has hitherto shown no tendency to vomit, or perhaps has posseted a mouthful or two, begins to vomit occasionally. The vomiting is not necessarily very frequent, perhaps only twice in the twenty-four hours, but the vomit is large and evidently consists of more than the last feed; moreover, it comes up with such force that it comes through nostrils as well as mouth. At the same time the bowels, which have been working with more or less regularity, become constipated, and the weight, which has been rising satisfactorily, ceases to increase and very soon begins to fall. In some cases it is this wasting rather than the vomiting which has aroused the mother's anxiety. On examination of the abdomen there is seen peristalsis of the stomach and the characteristic thickening of the pylorus is to be felt.

I shall proceed to consider this affection in detail, basing my remarks on my series of 248 cases. Unfortunately I find that in my notes I have sometimes omitted to record particular points, so that my figures will not on all points include the whole series.

This is one of the diseases in which sex incidence is as remarkable as it is difficult to interpret. Of 247 cases only 37 were girls, 210 were boys.

Place in family is much less definitely a predisposing factor than sex. In 114 cases out of 230 in which I have noted this point the infant was the first-born child; so that the proportion of first-born is about 50 per cent. I would point out that the proportion of first-born affected does not necessarily correspond to the liability of the first-born. In my opinion there is a special liability of the first-born to this, as also to other congenital abnormalities, but it is difficult to give any conclusive evidence of this, especially in these days when in many families there is only one child or two, so that the chance is considerable that a large proportion of persons showing any condition will be first-born.

In speaking of congenital hypertrophy of the pylorus as a congenital abnormality I do not mean to imply that the hypertrophy, or even the spasm that leads to hypertrophy, dates from birth; it is conceivable that it may do so, although the symptoms do not appear until the infant is about 2 to 4 weeks old. What is congenital is apparently some lack of stability, if I may put it so, in the harmony of gastric and pyloric relaxation and contraction, so that the child starts life with a machine which, although able to work passably well for a few weeks, is certain soon to get out of order. In this sense, at any rate, the disorder is congenital, and, like other congenital abnormalities, it is sometimes

repeated in the same family. Amongst my 248 cases there were four instances of two cases of this affection occurring in the same family.

The age at which the first symptom appears—and for this purpose I have regarded vomiting as the first symptom—will be seen from the following table of 195 cases in which this point was noted:

Week of onset.	No. of cases.	Week of onset.	No. of cases.
1st	30	6th	6
2nd	38	7th	1
3rd	57	8th	7
4th	35	9th	1
5th	19	12th	1

## SYMPTOMS AND DIAGNOSIS.

I propose now to consider the symptoms in detail with special reference to diagnosis.

Vomiting, constipation, and wasting: this is the combination which in any infant under 3 months of age should always suggest the possibility of congenital hypertrophy of the pylorus. The association of constipation with vomiting at any period of childhood should make one suspicious of serious organic disease, such as meningitis or some form of intestinal obstruction, and early infancy is no exception to this rule. The vomiting of digestive disturbance is likely to be associated with looseness of bowels rather than with constipation: there is also usually with it some abnormal appearance of the stools, whereas with congenital hypertrophy of the pylorus there is marked constipation and the stools are usually otherwise normal. The constipation is no doubt due to the smallness of the quantity of food which passes through the pylorus into the bowel, and the gradual disappearance of the constipation is one of the indications of lessening of the pyloric obstruction in cases which are treated by lavage of the stomach.

The vomiting varies remarkably in its frequency. There are cases, and I think the commoner, in which the vomiting is almost insidious in its onset, occurring at first perhaps only once or twice in twenty-four hours. The baby has posseted from time to time, and it was thought that this was due either to flatulence or to some indigestion; then a larger and more forcible vomit began to occur once or twice in the day, but there was no date to which the beginning of the trouble could be definitely referred. There are other cases in which upon a particular day the infant begins to vomit, never having vomited before, and the vomiting occurs after nearly every meal, so that hardly any food is retained. Naturally in the latter class of case the loss of weight is much more rapid than in the less acute cases. I have known such to lose weight at the rate of several ounces a day, whereas in the more common type, with vomiting perhaps twice daily, a loss of 5 or 6 oz. a week is more likely.

The character of the vomited material is worth observing, for it may give some clue to the state of the stomach. In the early stage it usually consists only of food, but as time goes on there is more and more tendency to vomiting of much glairy mucus, evidently pointing to a catarrhal condition of the mucous membrane, and this is often associated with considerable dilatation of the stomach; the stagnation of food not only distends the stomach but sets up a catarrhal condition of the mucosa, and sometimes brown shreds or even red clots of blood appear in the vomit. Occasionally, in spite of the situation of the obstruction in these infants, bilious material has appeared in the vomit. This is rare, but is of interest as showing that the closure of the pylorus is not continuous. If any proof were needed that the pyloric obstruction is intermittent, and is therefore due at least in part to spasm of the pylorus, it would be afforded by cases, not very rare in my experience, in which infants with peristalsis and tumour, proved subsequently by operation to be due to hypertrophy of the pylorus, have had intervals of two or three days, sometimes even as long as five days, when the vomiting has temporarily ceased entirely and food passes through the pylorus normally. I mention this not only because it throws light on the character of the obstruction, but also because it has sometimes raised doubts as to diagnosis, both in the parents' and in the doctor's minds, when the spasmodic nature of the obstruction has not been fully realized.

In this connexion also I would mention another feature which is usual in this disorder, though not peculiar to it—that each change of food is apt to be followed by lessening or cessation of the vomiting for twenty-four to forty-eight hours, after which the vomiting becomes as troublesome as

\* Delivered before the West Dorset Branch of the British Medical Association, November 25th, 1922.

before. This repeated temporary improvement is another source of error in diagnosis. A condition apparently so responsive to change of diet is thought to be simply a digestive trouble, and it is concluded that if only the right food could be found the trouble would disappear. So one finds that often food after food has been tried and the infant has gradually lost weight and strength before the possibility of pyloric obstruction is realized.

Now the diagnosis of congenital hypertrophy of the pylorus, unlike the diagnosis of many other disorders and diseases, is not a matter of opinion; it is demonstrable, and its demonstration consists in seeing waves of peristalsis in the hypertrophied and dilated stomach, and in feeling the hard and thickened pylorus. Visible peristalsis of the stomach in an infant is not necessarily an indication of any obstructive condition; its significance depends upon the degree of the peristalsis. Without organic disease of any sort a slight wave of peristalsis is sometimes to be seen in a thin infant towards the end of a meal, and I have thought this was specially noticeable in infants who were much subject to vomiting, apart from organic disease of any sort, but the waves are much less marked than those seen in congenital hypertrophy of the pylorus. Even the large wave which is such a striking feature of pyloric hypertrophy, the rounded bulging, varying in size from half a walnut up to half a Tangerine orange, and emerging from under the left costal margin to pass slowly across the epigastrium, separated by a depression from the succeeding wave, and this by yet another depression from another wave, is not necessarily pathognomonic of congenital hypertrophy of the pylorus. Exactly similar peristalsis has occurred in cases of stenosis of the duodenum, and I have seen one case in which such peristalsis occurred with complete obliteration of the duodenum. These duodenal cases are much rarer than pyloric obstruction.

Peristalsis of the stomach is certainly not in itself proof of congenital hypertrophy of the pylorus, though it may be admitted that when the peristaltic waves are large this is by far the most probable explanation.

The only absolute proof of pyloric hypertrophy, short of opening the abdomen and seeing it, is to feel the tumour. The pylorus in these cases is to be felt as a small barrel-shaped hard tumour, which, as palpated through the abdominal wall, gives the impression of varying in size from the thickness of an ordinary lead pencil up to that of a hazel nut. Its position is usually about 1 to 1½ inches above the level of the umbilicus, close to the right side of the vertebral column, so that it is usually necessary to press slightly inwards and very deeply under the right rectus muscle towards the vertebral column. The characteristic feature of the tumour is its disappearance, so far as palpability is concerned, when the pylorus is relaxed, so that, like an intussusception, the tumour may be quite obvious at one moment and a minute or so later it may not be felt. This variability in the hardness of the tumour is important in diagnosis, for it may be necessary to distinguish between hard scybala and the tumour due to hypertrophy of the pylorus. The contraction and hardening of the pylorus may be stimulated, when its position has been located, by gently kneading with the finger, which often helps considerably in demonstrating the tumour. How often is this tumour to be detected? Twice only in my 248 cases have I failed to feel it definitely, and one of these was moribund, so that examination could not be very thorough. Allowing for such rare failures, I think one would be right in saying that the tumour is to be felt in all cases, if sought in the proper way. The characteristic tumour makes the diagnosis certain, and in such a serious condition, if certainty is attainable, we have no right to be satisfied with anything less than certainty; for our diagnosis may involve an extremely grave operation. And yet I find that it is only seldom in cases seen in consultation that the tumour has already been felt.

In the first place, let it be recognized that, whilst in some cases the tumour is found at once and with ease, there are others in which it is only to be found by painstaking and prolonged searching. I have sometimes had to see an infant twice, or even three times, before I could be certain of the tumour.

If a casual poking of the finger-tips into the abdomen is expected to discover the tumour the result will usually be failure; one must be prepared to sit down before the infant, have a feed given, and patiently palpate the abdomen, it may be, for ten or fifteen minutes before the tumour is detected, and even then, if the movements of the stomach happen to be

sluggish, one may fail to find the tumour until more brisk peristalsis occurs.

It is always advisable to have the infant fed during the examination, and this for three reasons:

1. The abdomen becomes relaxed, so that deep palpation is easy.
2. During the progress of the feed peristalsis of the stomach begins, and it is at this time that the pylorus is most likely to be felt.
3. If a full feed is given the pylorus is displaced somewhat downwards and to the right, so that it is more easily reached.

The cases in which the pyloric tumour is most difficult to detect are those in which the pylorus is, so to speak, tucked up high in the liver, and it is in such cases particularly that the giving of a large feed may assist detection of the tumour.

#### PROGNOSIS AND TREATMENT.

In 232 of my cases I have a record of the results (in 16 the notes were defective and the result not recorded); there was recovery in 156, death in 76. Of the fatal cases, 7 were in such an extreme condition of exhaustion when seen that either no treatment was possible or, at most, lavage was only just begun, and the child died within a week or less, several within twenty-four or forty-eight hours. These I shall omit from consideration, as they hardly affect the question of prognosis or treatment, except to emphasize the importance of early diagnosis. One may say, therefore, that 225 cases are available for considering the effect of treatment, and of these 156 recovered, 69 died. These figures, it must be remembered, cover a period of twenty-four years, and therefore include cases seen at a time when treatment was more tentative than it is now, and when surgery was invoked rather as a last and desperate resource than as an early and deliberate choice, which it usually is to-day. There is another point which must be considered if prognosis is to be based on statistics—namely, whether the figures are from cases treated in hospital or from cases treated in private, that is, in nursing homes or in the patient's own home. My own experience—and on this point I believe the experience of others has been the same—is that hospital results in this disorder are, for some reason difficult to ascertain, much less satisfactory than private results, and this holds good whatever method of treatment is adopted. If the figures given above are divided into these two categories the difference is evident:

		Recoveries.	Deaths.
Private cases	...	113	14
Hospital cases	...	43	55

No single cause seems sufficient to account for these differences; great efforts are made to obtain at least as good results in hospital as in private practice, and to some extent hospital results have improved in recent years. One factor which applies rather to my earlier cases than to those in recent years was the use of wet nurses, which certainly saved several of my private cases after operation; this has rarely been practicable in hospital. Anyone who is familiar with the treatment of infantile disorders in hospitals knows how often infants do badly with any condition, especially with any gastric or intestinal disorder, amongst a number of other ill children; they are specially apt to develop diarrhoea, and go down with symptoms suggestive of gastro-enteritis. Infants do best segregated as much as possible. This has, I think, something to do with the poor results in the hospital treatment of these pyloric cases. Whatever the explanation may be this difference has to be borne in mind in prognosis.

I pass now to the consideration of particular methods of treatment. Twenty years ago recovery by operation was regarded as a notable triumph of surgery, but since that time surgical technique has made such strides that recovery is now a commonplace; indeed, there is a tendency to lose sight of the fact that complete recovery can take place without operation at all. So far from operation being essential in all cases, there are some in which without special treatment of any kind beyond painstaking and efficient regulation of the feeding, generally in the direction of reducing the food to small quantities at short intervals, the tumour and peristalsis have gradually disappeared, and after many weeks or months of hovering on the verge of collapse the infant has completely recovered. Amongst my 156 recoveries there were six which were treated in this way,

and one in which after lavage had been perseveringly tried without success, the infant eventually recovered with prolonged care in feeding. Similar cases have been published by other observers. I mention this mode of treatment only as showing that the hypertrophy and obstruction can pass away spontaneously, but the chance of recovery by such treatment is probably extremely small. It must be remembered that a large proportion of the cases which have been eventually treated by other methods have been treated at first, and sometimes for several weeks, by dieting, and it is the failure of such treatment which has led to other methods being used.

Another line of treatment which has had so many successes that in former years it seemed only right to try it in all cases in the hope of avoiding what at that time was the much graver risk of operation, is stomach washing—lavage. Of 78 cases treated only by lavage 43 recovered, 35 died. It is only right to add that in former years I adopted this treatment always before resort to operation, so that these figures represent only those in which the result of lavage seemed sufficiently promising to justify continuance of it, a practice which eventually failed in some cases, as my figures show. But there are many others in which after lavage had been tried for some days or weeks the result, though sometimes a definite improvement, was not thought sufficiently good to justify postponing operation, so that my operation cases include many in which lavage had previously been done without effecting a cure.

Lavage, apart from its uncertainty of ultimate result, has drawbacks. Not all babies tolerate lavage; there are those who become so collapsed and exhausted by it that the lavage has to be abandoned. When it has been long continued I have known it to cause gastric irritation, so that the washing came back blood-stained and lavage had to be diminished or stopped. At the best it is only after many weeks of daily lavage, usually twice daily for a time and then once daily, that the condition is cured. I have generally reckoned twelve to sixteen weeks as the usual period during which lavage is necessary in cases which are cured by it. The gradual disappearance of the peristalsis and tumour under this treatment is very instructive as to the spasmodic origin of the hypertrophy. The vomiting ceases gradually, and is usually entirely stopped some weeks before the peristalsis and tumour have disappeared. The long duration of this treatment, the failure at first to gain weight, and then, after a week or two, the slow and unsteady gaining, make a trying ordeal for the parents, and the daily lavage necessitates either a specially trained nurse or a large amount of medical attendance, which is sometimes a practical difficulty.

With all its drawbacks, however, lavage has had sufficient successes, as my figures show, to justify its retention as a method of treatment which may be the best one to adopt in particular cases. Where the weight is only slowly falling and it is evident that a considerable amount of food passes through the pylorus, it may be right to try lavage and judge by daily weighing whether operation can still be postponed; but if the weight continues to fall, even for a few days, lavage should be abandoned. In cases where lavage succeeds the weight commonly ceases to fall, but does not rise during the first few days, perhaps not for a week or ten days, and then it begins slowly to rise. (I assume that the feeding is carefully regulated.)

In the decision as to whether operation or lavage should be the first line of treatment the possibility of obtaining surgery specially experienced in this disorder must weigh greatly. It makes a very great difference if the services of some surgeon who has operated upon many of these cases of congenital hypertrophy of the pylorus are available. Another point, and one of first-rate importance in the decision as to treatment, is the possibility of retaining the mother's milk. If the mother is still suckling the prolonged anxiety and the disturbances of suckling which are likely to be entailed by the lavage treatment will almost certainly end in loss of the breast milk, and this undoubtedly diminishes the prospect of success if operation becomes a necessity. My own feeling, therefore, is that when the mother is breast-feeding her infant it is usually the wisest course to proceed at once to operation, so that only with an interruption of forty-eight hours to allow for recovery from the immediate disturbance of operation the infant may continue the breast milk. Usually after a few hours' feeding with some watery solution such as glucose, and then a few more hours' feeding with milk pumped from the breast, the infant can within two or three days return to breast-feeding.

But if it is decided to operate there is still the question of method, and on this point the physician can only speak from his experience of results. Various operations have been tried; some have been abandoned by common consent. Pylorectomy, pyloroplasty, gastro-enterostomy are now things of the past so far as congenital hypertrophy of the pylorus is concerned. In two of my cases years ago gastro-enterostomy was done; both recovered, but in all the rest of the 139 cases in which operative treatment was adopted either forcible dilatation of the pylorus—that is, a modified Loreta operation—or in the last five years the Rammstedt operation, was done. The results of the various modes of treatment are perhaps best seen in the tabulated summary.

Results of Various Methods of Treatment of Congenital Hypertrophy of the Pylorus.

Method of Treatment.	Private Cases.		Hospital Cases.	
	Recovery.	Death.	Recovery.	Death.
Simple feeding ...	5	0	2	1
Lavage ...	24	6	19	29
Gastro-enterostomy ...	2	0	—	—
Forcible dilatation ...	74	6	12	16
Rammstedt ...	8	2	10	9

Anyone who has seen the Rammstedt operation—that is, a longitudinal incision through the peritoneal coat and muscular layers of the pylorus, leaving the mucosa intact—can hardly fail to have been impressed with its simplicity and rapidity, and it has already become the generally approved operation for congenital hypertrophy of the pylorus. But, as my figures show, it is by no means free from danger. The deaths from the Rammstedt operation in my fatal cases have, I think, all been within a few days afterwards; sometimes from bleeding from the pyloric incision into the peritoneal cavity, sometimes from shock, sometimes from collapse within two or three days, but always (except in one case where the child died when the recurrence of symptoms necessitated a second operation) as a direct result of the operation. So that although it offers great advantages and is no doubt the operation which most surgeons will adopt, it has a considerable mortality, and at present I have but seldom had it done in my private cases. Indeed, the results of forcible dilatation have been so good, especially in recent years, that it is hardly likely better could be obtained.

The operation of forcible dilatation has been done in nearly all my cases by Mr. F. F. Burghard, and the proportion of recoveries in the private cases hardly does justice to his recent results. These in the past few years show a much higher proportion of successes. In the past eight years Mr. Burghard has performed this operation on forty-six of my private cases, with only one death. It is clear that this operation, as done by him, has given results at least as good as those obtained by the Rammstedt operation. But this no doubt depends very largely on the particular operator and cannot be taken as proving that the operation itself is as good as, or better than, the Rammstedt method; indeed, in the hands of some surgeons it has had very little success. The hospital mortality of these forcible dilatation cases has, in my experience, been much less often due directly to the operation than is the mortality of the Rammstedt procedure; death has occurred more often after many days or weeks from gastro-intestinal disturbance or marasmus.

By whatever treatment recovery is obtained the recovery seems to be complete. It is true that recurrence has taken place both with Rammstedt operation and with the forcible dilatation, but this happens within ten days after the operation; it occurred three times amongst my earlier cases treated by dilatation, necessitating a further dilatation, which in each case was followed by recovery. It happened once also amongst those treated by the Rammstedt method, but in this case a second operation by the same method proved fatal. With increased experience of the degree of stretching needed in the one case and of the length of the incision needed in the other, recurrence is now hardly to be feared.

I have seen or heard of many of my cases years afterwards. The hypertrophy of the pylorus, whether treated by simple feeding, lavage, or operation, has seemed to leave no after-effect; they have been as a rule particularly healthy and fine children.

# TEN CASES OF OVARIOTOMY IN WOMEN OVER 70 YEARS OF AGE.

BY

HERBERT R. SPENCER, M.D., B.S., F.R.O.P.,  
OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

OVARIOTOMY on women over 70 years of age is so uncommon as to justify the publication of a complete series of cases. The advanced age of the patients introduces pathological, clinical, and therapeutical features which are worthy of consideration.

The following ten cases have been met with amongst 625 ovariectomies I have performed.

## CASE I.

M. A. F., aged 82½ years. This case was published in the *BRITISH MEDICAL JOURNAL* in 1893 (ii, 1271). The patient was, so far as I know, the oldest upon whom ovariectomy had been performed up to that time, except Homans's patient, who was apparently a few weeks older. The tumour was a multilocular cyst of the size and shape of a cottage loaf. There was some mental wandering, bronchitis, and loss of control of faeces and urine during convalescence; but a good recovery ensued and the patient was in excellent health eleven months later. The patient's mother died at the age of 76, two sisters at 70, and one was still living at the age of 79.

## CASE II.

E. F., a widow aged 71, who had had fifteen children, two miscarriages, was admitted to University College Hospital on May 10th, 1898, complaining of enlargement of the abdomen and prolapse of the womb for four years, and of a dirty vaginal discharge, sometimes tinged with blood, which had been present for some months. For six months she had had difficulty and frequency in passing water; sometimes there was an aching pain in the lower abdomen and back; the bowels were confined.

Menstruation began at 17, was regular, not excessive, and lasted for three or four days; it ceased at 50.

The patient's father and mother died at the age of 78. The abdomen was greatly distended, the half-girth being 22½ inches on each side, while the measurement from ensiform cartilage to pubes was 20½ inches. A large, evidently multilocular, ovarian tumour distended the abdomen. The vagina was inverted and had a large ulcer on it. The os was healthy. Under treatment by boric acid douches the ulcer gradually healed by July 1st.

On July 11th, 1898, ovariectomy was performed. Ventrifixation was also performed by means of the ligature on the right pedicle, and a second silk ligature passed under the left round ligament, tying the left side of the uterus to the abdominal wall; this ligature was removed on the seventh day. The abdominal incision was closed with silkworm gut passed through the abdominal wall, buried silk for the fascia, and horsehair for the skin. The operation lasted thirty-four minutes.

The tumour was a multilocular ovarian cyst without papilloma or solid growth, and contained 15½ pints of fluid. There was very little shock after the operation; a little sickness occurred at 5 p.m. and 11 p.m. The patient slept a good deal in the evening, was comfortable except for a slight pain in the back, and passed urine spontaneously. Some pain next day was due to pressure of a too tight bandage, and was at once relieved on relaxing the bandage. Flatus was passed on the second day.

The recovery was simple, the temperature only once reaching 100° after the operation. The wound healed by first intention, and the patient left the hospital on August 13th. Seen on October 25th the scar was sound, but there was still proclivity of the vagina and cervix. For a few days after the operation the patient was rather sullen, at a time when she slept badly; but later her spirits became normal.

## CASE III.

L. B., a married woman aged 70, who had had two children naturally, was admitted to University College Hospital on May 19th, 1908, complaining of a tumour in the abdomen which she had noticed for six months, increasing in size and accompanied by pain in the lower part of the back; she also had pain on passing a motion except when the bowels were relaxed with medicine. Menstruation had always been regular.

The patient was rather feeble. The abdomen was irregularly distended, chiefly below the umbilicus and on the right side by a cystic tumour which reached up to within one inch of the umbilicus and projected into Douglas's pouch, displacing the small atrophied uterus slightly forwards and to the left. The tumour fluctuated and was evidently a multilocular ovarian cyst.

Ovariectomy was performed on May 25th, the pedicle being tied with silk and the surface of the stump turned in and stitched over with fine silk. The abdominal wall was closed with through-and-through stitches of silkworm gut and buried continuous silk for the peritoneum and sheath of rectus. The operation lasted fourteen minutes. There was no abdominal discomfort or shock, and very little vomiting afterwards. The wound united by first intention.

The temperature rose daily to 100° for the first five days, and in the second week on two occasions reached 101.2°; but after the sixteenth day it did not rise above 99.5° and was normal when she was discharged well on June 30th.

The tumour was a multilocular cyst of the left ovary with no solid growth or papilloma; it weighed 2 lb. 7½ oz. The right ovary was normal and was not removed. No cause for the rise of temperature was discovered; there were no rales in the chest, and no pain or mental disturbance.

## CASE IV.

Mrs. B., aged 74 (two children, no miscarriage), was seen by me at New Barnet, in consultation with Dr. Elam, in May, 1914. She had lost a good deal at the menstrual periods, which ceased at the age of 50. At the age of 71 she had a grave attack of hemiplegia, for which Sir Thomas Barlow saw her in consultation. For nearly a year it was thought she would not recover. She gradually got about, but had since suffered from phlebitis in the veins of the arms and legs. Early in 1914 she began to complain of pain in the lower abdomen and of difficulty in micturition and defaecation. A tumour was discovered reaching up nearly to the umbilicus, most marked on the left side. It was fixed, was diagnosed as an adherent ovarian tumour, and was removed (at the patient's house) with some difficulty, on account of the strong adhesions, on May 4th, 1914. In cutting the tumour free the bladder was opened for about two inches and the hole was closed with silk sutures, not involving the mucous membrane. A drainage tube was inserted. The wound healed by first intention, except the track of the drainage tube, which closed quickly by granulation. There was no trouble after the operation.

The tumour was a multilocular ovarian cyst, with no solid growth or papilloma, the cyst having the usual columnar epithelial lining.

The patient remained well for more than six years after the operation, but died of hæmatemesis, thought to be due to gastric ulcer, when over 80 years of age, on October 15th, 1920.

## CASE V.

C. G., a virgin aged 71, was sent to me by Dr. Goulet on February 17th, 1916, complaining of swelling of the abdomen and aching pain for the past six months. Menstruation had ceased at 50. It had not been very regular at first, but became more so later on, and was always attended with a good deal of pain. The patient had lately suffered on most days from vomiting. On six occasions she had had to have a catheter passed for retention of urine. The bowels were confined. She had really had pretty good health; but when a young woman, having a "displacement" of the womb, she was kept in a recumbent position for twenty years, always being carried if she left her room; she suffered much from sickness during this time. The legs were not swollen and she had been getting thinner. A slight cough sometimes troubled her, but there was no expectoration. The tumour had been discovered by the doctor a fortnight before I saw her.

The abdomen was greatly distended by a multilocular ovarian tumour considerably larger than a uterus at term. The uterus was small and freely movable, and the lower end of the tumour could be felt in front of the body and movable apart from it.

A multilocular ovarian tumour of the left side which contained neither new growth nor papilloma was removed in a nursing home on February 20th, 1916. The right ovary, atrophied, was not removed. The patient made a simple recovery. The wound healed by first intention. She was in fairly good health in February, 1923, seven years after the operation. A sister is living at the age of 86.

## CASE VI.

C. D., aged 70½ years (four children, no miscarriage), was admitted to University College Hospital on July 18th, 1918. Her last child was born thirty years ago. She complained of being suddenly seized with pain in the abdomen when out walking recently. A doctor whom she consulted found an abdominal tumour, which had greatly increased in size during the last month.

Menstruation began at 17 and ceased at 54. It had been regular every four weeks, lasting seven days, unaccompanied by pain. The flow was rather free, fifteen diapers being used; micturition was frequent; the bowels regular. The patient had lost a good deal of flesh lately.

On examination an abdominal (evidently multilocular ovarian) tumour, as big as the uterus at term, reached up to the ensiform cartilage. The uterus was atrophied and movable. Behind and to the left side was a hard tumour, as big as a hen's egg, which appeared to be an ovarian fibroid. The large abdominal tumour could not be felt per vaginam. The case was diagnosed as an ovarian fibroid on the left side and a multilocular ovarian cyst on the right.

The large tumour was found to affect the left ovary when removed on July 20th, 1918, through a four-inch median abdominal incision; on tapping this cyst about a gallon of straw-coloured fluid escaped. The pedicle was tied and stitched over with silk. A small cyst was found in the right ovary, which was also removed. The hard tumour proved to be a subperitoneal calcified fibroid of the uterus and was not removed. The abdominal wound was closed with through-and-through stitches of silkworm gut, continuous silk for the peritoneum, interrupted silk for the sheath of the rectus, and silkworm gut for the skin.

The patient was a little sick after the operation and required the use of the catheter. She made an uninterrupted recovery, and left the hospital on August 12th, 1918.

The tumour was a multilocular cyst, quite smooth on the external surface and free from adhesions, and showed a few dilated lymphatics; an accessory ostium was present in the place of a tube. The inner surface was irregular and covered in places with pigment and thin patches of papilloma up to the size of a raspberry, and in a few places with little solid white growths not bigger than a grain of wheat or a pin's head. There was no extensive metastatic papilloma and no other solid growth. The right ovary measured

FIG. 2 (Case x).—Showing a few adhesions and collapsed cyst wall perforated at one spot. (Three-quarter natural size.)

FIG. 3 (Case x).—Section of tumour, showing several cysts; below, partly filled with blood clot, the ruptured cyst. (Three-quarters natural size.)

was considerably distended, and there was a large amount of free fluid in the abdomen. Through this a firm mass could be felt three inches to the right of the left anterior superior spine; another mass could be felt by dipping on the right side, the whole mass reaching nearly up to the umbilicus, and being covered in front by free fluid. A very large rectocele protruded from the vulva and rendered examination of the vagina difficult; but a hard irregular mass fixed to the left pelvic wall was felt to the left of the cervix and in Douglas's pouch. The glands in the groins were not enlarged. The urine (sp. gr. 1010) was free from albumin and sugar.

The case was diagnosed as malignant disease of the ovaries and peritoneum, probably secondary to cancer of the stomach, which was suggested by the wasting and the vomiting, and by the pain and tenderness in the epigastrium. The patient was kept under observation in the ward, and gradually the oedema of the legs disappeared. At the same time the vomiting gradually ceased, and the amount of free fluid in the abdomen lessened, though it still was so considerable as to render palpation difficult. The tongue was rather dry, but fairly clean, and the patient remained cheerful. The temperature, which was 99.6° on the day of admission, and 99.4° the next day, was afterwards usually about 98°, and only reached 99° on one occasion during her long stay in the hospital. The pulse beat was about 90. The patient had been in the hospital for two months, but except for the extreme emaciation she had improved; especially the disappearance of the oedema of the legs was regarded as a good sign. She weighed 7 st. 7 lb. on admission, 7 st. on November 9th, and the same on November 28th. On that day, on examining the abdomen, I thought the hard abdominal tumour moved as one large mass from side to side, floating in the fluid though anchored below; and, as such a tumour could hardly be malignant, I diagnosed it as an ovarian fibroid which had probably ruptured.

At the operation on December 2nd, 1922, this was found to be the case. On incising the abdominal wall several pints of free fluid escaped and the large tumour was found to be free from adhesions except in Douglas's pouch, where two cystic portions had ruptured and led to adhesions there. They were separated without difficulty, leaving a layer of mucoid exudate at the bottom of Douglas's pouch, and the tumour was removed. It occupied the right ovary and its pedicle was adherent to the mesentery of the appendix, which lay in the small pelvis, but was apparently healthy. The pedicle was tied and stitched over with silk; the adhesion to the meso-appendix was also ligatured, and a string-like band which passed from the small intestine towards the fundus of the bladder was tied and excised. The uterus and left ovary were atrophied and were not removed. The wound was stitched with through-and-through stitches of silkworm gut, silk (continuous for the peritoneum and interrupted for the fascia) and silkworm gut for the skin. The operation lasted forty minutes. The anaesthetic was open ether.

The recovery after the operation was ideally simple. The wound healed by first intention and the temperature was normal or subnormal throughout the convalescence. The patient got up on December 27th and left the hospital quite well on January 3rd, 1923.

The tumour was hard, rounded, somewhat triangular, and flattened, measured 7 in. by 7 in. by 3½ in. and weighed 3 lb. 6½ oz. It had some small prominences on the surface and was irregularly depressed where the larger ruptured cyst lay. The tumour

was dusky red in places, especially below (where it had ruptured), and had several large veins coursing over its surface. At two places near the surface it had become cystic, one of the cysts being as big as a duck's egg, the other as big as a grape. Both these had ruptured, causing adhesions which were visible in the neighbourhood (see Fig. 2). The collapsed wall of the larger cyst lay in a depression of the tumour, and the rupture might have escaped notice on superficial examination; but the collapsed cyst could be picked up with the point of a needle, and by introducing a fine hollow needle into the cyst through the solid part of the tumour and injecting fluid the cyst and the hole in its wall were easily demonstrated.

On section through the tumour it was found to have the typical structure of an ovarian fibroid, degenerated in several places; the degeneration had advanced to the extent of forming a considerable irregular cavity in the middle of the tumour filled with jelly-like contents and having an irregular wall with bridges of tissue crossing it (Fig. 3). Another cyst near the surface as big as an almond had a smooth and slightly blood-stained wall. In addition the large cyst which had ruptured was partly filled with blood clot and the smaller ruptured cyst exuded clear yellow fluid. A section at the hilum showed the tumour sharply demarcated from the normal ovarian tissue. There was an accessory ostium in the Fallopian tube.

Microscopic examination showed the tumour to be a fibromyoma, being mostly composed of bundles of muscular tissue which had undergone hyaline degeneration and in places was oedematous or liquefied into cysts. The ovarian tissue at the hilum had also undergone marked hyaline degeneration.

#### Frequency of Ovariectomy in Women over 70 Years of Age.

The above 10 cases occurred amongst 625 cases of ovarian tumour operated on by me, the frequency being 1.6 per cent. They are the only cases I have seen—that is, every case seen has been operated on.

Amongst Spencer Wells's first 500 cases there was no patient over 70; amongst his second series of 500 two cases (aged 70 and 77) occurred; one of them died from the operation. No doubt a selection of cases for operation had been made, as was not unusual in the early days of ovariectomy. Spencer Wells's percentage of frequency, as the figures stand, is 0.2 per cent., or a little more, for in 15 cases of his second series of 500 the age is not given.

Howard Kelly<sup>2</sup> published 5 cases of ovariectomy in women over 70 years of age which occurred amongst 150 cases; one of these, however, was only an exploratory operation, was operated upon on May 2nd, 1896, and was published as a "recovery" ten days later; there were thus only 4 cases in which the patients were over 70 years of age in 150 ovariectomies (2.6 per cent.).

At the Würzburg clinic<sup>3</sup> amongst 100 cases of ovariectomy, and at the Jena clinic<sup>4</sup> amongst 257, making together 357 cases, there was no patient over 70 years of age.

Ten Cases of Ovariectomy in Patients over 70 Years of Age.

Initial.	Age.	Children.	Abortions.	Duration in Months.	Date.	Side.	Drainage.	Fascia Sutured.	Adhesions.	Operation.	Recovered.	Remarks.
M. A. F.	82	5	0	17	Dec. 19, 1891	L.	No	No	A few shreds on right side	L. ovariectomy	Yes	L. ovarian tumour, pedicle twisted 1½ turn; R. ovary normal, not removed. Anaesthetic, gas and ether.
E. F.	71	15	2	34	July 11, 1893	R.	No	Yes	No	R. ovariectomy and hysteropexy	Yes	Enormous R. ovarian cyst with procidentia uteri; pedicle tied to abdominal peritoneum and a ligature passed through abdominal wall around L. round ligament. Anaesthetic, gas and ether.
L. B.	70	2	—	14	May 23, 1908	L.	No	Yes	No	L. ovariectomy	Yes	Patient very feeble; operation very easy. Tumour size of ostrich egg. R. ovary normal, not removed. Anaesthetic, chloroform.
B.	74	2	0	45	May 4, 1914	L.	Tube three days	Yes	Dense to abdominal wall and bladder (opened)	L. ovariectomy	Yes	Patient had severe attack of cerebral apoplexy 3 years before; was ill for 5 months and thought on many occasions to be dying. R. ovary normal, not removed. Anaesthetic, ether. Died of haematemesis; Oct. 15th, 1920.
C. G.	71	0	0	20	Feb. 20, 1916	L.	No	Yes	No	L. ovariectomy	Yes	Virgin. Large left multicystic cyst size of uterus at term noticed 6 months; no solid growth, no papilloma. R. ovary small, not removed. Anaesthetic, ether. Living in fair health in February, 1923.
C. D.	70	4	0	25	July 20, 1918	L. R.	No	Yes	No	Bi-lateral ovariectomy	Yes	L. multicystic cyst size of uterus at term; calcified fibroid in uterus. R. ovary small, cystic, removed. Anaesthetic, ether. In good health, January, 1923.
I. E.	71	2	0	53	Dec. 21, 1918	L.	No	Yes	To omentum and abdominal wall; of omentum to sac of hernia	L. ovariectomy and herniotomy	Yes	Large multicystic cyst with no solid parts or papilloma; omentum in left inguinal canal reduced, adherent to mouth of sac (closed by purse-string suture). Anaesthetic, chloroform and ether. In good health, January, 1923.
L. A.	70	11	0	23	May 8, 1919	R.	No	Yes	No	R. ovariectomy	Yes	R. large multicystic cyst (no solid growths or papilloma). L. ovary normal, not removed. Anaesthetic, chloroform followed by (closed) ether. In fairly good health, January, 1923.
E. S.	70	7	3	32	July 2, 1921	L.	No	Yes	No	L. ovariectomy	Yes	L. ovarian fibroid (2 lb. 10 oz.), ruptured, free fluid in abdomen. Patient in good condition, cheerful. Anaesthetic, ether. In good health, February, 1923.
S. S.	71	0	0	40	Dec. 2, 1922	R.	No	Yes	To Douglas's pouch and mesentery of appendix	R. ovariectomy	Yes	R. ovarian fibroid (3 lb. 6½ oz.), ruptured, free fluid in abdomen. Patient very emaciated, cachectic, but cheerful. Anaesthetic, ether.

mortality rate as 12.3 per cent., but, as the result was not mentioned in 4 cases, there were really 16 deaths in 126 cases = 12.6 per cent.; adding my 9 hitherto unpublished cases and the patient of 92½ mentioned above, gives 136 cases with 17 deaths, or 12.5 per cent.—that is, 1 patient in 8 died from the operation.

If all the cases operated on had been published it is possible that the mortality would be higher; for if we take Kelly and Sherwood's table<sup>4</sup> of those ovariectomists who have published at least 5 cases and add my cases we get the results shown in the following table:

Operation.	Cases.	Deaths.	Remarks.
Halliday Croom ...	6	2	One had cancer of uterus; the other was a parovarian cyst.
I. Homans ... ..	12	3	One was a sarcoma, the other benign.
A. Martin ... ..	5	1	Embolism.
Werth ... ..	5	0	
H. R. Spencer ...	10	0	
Together ...	38	6	A mortality rate of 15.7 per cent.

The mortality is shown in Wiel's table<sup>18</sup> to be very high in malignant cases (which are fortunately rare), 4 out of 5 cases having succumbed; and in parovarian cysts, 2 out of 4 having died. One of the 8 cases of fibroma died (12.5 per cent.). The low mortality of the 17 recorded cases over 80 years of age (5.8 per cent.) has been already mentioned.

*Remarks on Ovariectomy in Old Women.*

These patients have outlived the allotted span of life show in their own persons a constitution of more than usual strength and in their family histories a tendency to longevity. If their organs are sound and the patients are not too fat they are good subjects for operation, especially if they are of a cheerful temperament.

The special points to be borne in mind in operating are their waning strength, their tendency to mental disturbance, and their liability to bronchitis and pneumonia. With regard to the anaesthetic, I think infiltration and spinal anaesthesia are *generally* unsuitable, as liable to upset the patient's mental equilibrium, though Igel,<sup>19</sup> Wechsberg,<sup>20</sup> and Pfannenstiel<sup>21</sup> have published very successful cases operated on under local anaesthesia, which offers many advantages for a simple ovariectomy in a courageous patient. I think ether is usually preferable to chloroform unless bronchitis be present. I should prefer to postpone operation if the weather were severe. The operation should be performed as rapidly as possible, with due regard to careful suturing. In case of urgency the abdominal wall may be sewn up with through-and-through stitches of silkworm gut by what I call the "reversed-B" suture, the loop of the B apposing the cut edges of the sheath of the rectus. This shortens the operation by *several minutes*, ensures good apposition of the fascia, and leaves no buried stitch. The head of the patient's bed should be screened from draughts, and the bed should be warmed. Old patients bear cold badly. When King David was old and stricken in years, though they covered him with clothes, yet he gat no heat.<sup>22</sup> The patient should be propped up in bed to prevent hypostatic pneumonia, and sedatives (not morphine) should be given, preferably by the rectum, if sleeplessness occurs.

It is fortunate that malignant tumours are rare in these patients, and a consideration of the results of ovariectomy for benign tumours in women over 70 years of age shows that the operation may be undertaken without selection of cases with every prospect of success, and the patients may survive beyond the fourscore years of the palmist, and yet their days may not be "but labour and sorrow."

# MAN'S POSTURE: ITS EVOLUTION AND DISORDERS.

GIVEN AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

BY

PROFESSOR SIR ARTHUR KEITH, F.R.C.S., F.R.S.,  
CONSERVATOR OF THE MUSEUM.

CONSERVATOR OF THE MUSEUM.

[Abstracts.]

LECTURE IV.—THE ADAPTATIONS OF THE ABDOMEN  
AND OF ITS VISCERA TO THE ORTHOGRADE  
POSTURE.

VERY early in my inquiries I became impressed by the fact that in the anthropoid or orthograde apes the viscera of the abdomen were very human in shape and arrangement, and that they were fixed to the walls of the cavity in almost the same manner as they are in the abdomen of man. On the other hand, a distinctly different pattern prevailed in the bellies of pronograde monkeys, even in the higher kinds, which are most akin to the gibbons in point of structure. It became apparent; then, as we have seen - to be the case with the spine and with the thorax, that the chief of these features in the human abdomen which we recognize as postural adaptations came into existence at that remote period when the gibbon type of anthropoid was evolved; these postural adaptations became further perfected with the appearance of the great anthropoid type, and reached their culmination in the human body with the evolution of the plantigrade mode of progression.

## HOW ARE VISCERA SUPPORTED?

At the time I was making these inquiries my conception of the mechanism which supported and kept the abdominal viscera in place was crude and mechanical. I supposed that when we stood up the organs within the abdomen were suspended by their mesenteries much as our coats hang from pegs within a wardrobe. I accepted a belief, then widely current, that in the erect posture a negative pressure or suction arose under the diaphragm and that thus the pressure of the atmosphere assisted in visceral support. Soon after I went to teach anatomy at the London Hospital in 1895 a series of events happened which showed that the mechanism involved in supporting the abdominal viscera was infinitely more complex than had been generally supposed. My attention had been attracted by certain dissecting-room subjects in which the abdominal organs were placed at an abnormally low level, as if their supports had given way. Of 71 subjects I found 10 in which the diaphragm and the organs within its domes were 2 inches or more below what was the usual level; in 15 other subjects there was a partial dropping of the viscera. My friend Dr. Christopher Addison, who had not then taken on the cares of statesmanship, had published very exact observations on the position of the abdominal viscera of 40 subjects; in 2 of them the upper abdominal viscera had dropped downwards to a marked extent, in 10 there was present a condition of partial prolapse affecting one or more organs. Then, when I was regarding this matter as one of merely anatomical interest, there appeared, in 1899, Dr. Franz Glénard's great volume entitled *Les Poses Viscérales*; he had become interested in the sagging of the abdominal viscera from a clinical point of view as early as 1885; in the patients who crowded to Vichy for the cure of dyspepsia and neurasthenia he found the condition of enteroptosis to be very common. In seeking for an explanation of how the dropping of viscera came about I turned to the out-patient department of the London Hospital, where an *x-ray* apparatus had been installed at an early date. It was possible then for all of us to examine the position of viscera in the thorax and abdomen of the living—particularly the organs which occupy the domes of the diaphragm. It became clear to everyone then that the viscera in the upper segment of the abdomen formed part of a respiratory piston. The upper end of the piston is covered by the diaphragm. When that muscle contracts during inspiration the upper end of the piston moves in a downward and forward direction; the piston is returned by a contraction of the muscles of the belly wall; the visceral piston is not only supported by muscles, it is delicately poised, in all phases of respiration, between the opposing

muscular groups. In those in whom the abdominal type of respiration is well developed the respiratory piston has a stroke of 3 inches, or even more when a deep breath is taken. Such observations compelled one to reconsider the mechanism of visceral support.

#### INTRA-ABDOMINAL PRESSURES.

It was an easy matter to show that subdiaphragmatic suction had nothing to do with keeping the viscera up. When the interior of the cardiac end of the stomach—which lies within the left dome of the diaphragm—was connected with a manometer the intragastric pressure was found, when the subject of the experiment was standing or sitting, to vary between +3 and +5 mm. of mercury. It was only when extreme inspiratory efforts were made to raise and expand the chest that a slight negative pressure appeared. When the subject lay on his back the intragastric pressure rose to 16 mm. Hg. On consulting literature concerning this subject I found my observations were not new; they had been made several times before. Pressures taken within the rectum when the living subject was standing in an easy posture throws further light on the mechanism of visceral support. The intrarectal pressure in these circumstances varied between 15 to 20 mm. Hg. Now if the whole weight of the semi-fluid column of abdominal viscera—360 mm. in height, and with a specific gravity of 1.50—rested on the floor of the pelvis, the intrarectal pressure ought to have been twice the amount observed; there must be, therefore, a suprapelvic mechanism which partially sustains the weight of the visceral column. This clearly cannot be the system of mesenteries and ligaments which pass from the viscera to the walls of the abdomen, for when the abdominal walls are measured from a dead subject, and the trunk is placed in the upright position, the contents of the abdomen, liver, stomach, spleen, and great and small intestine slip downwards until they hang from their mesenteries and ligaments. The descent of the upper organs amounts to about 3 inches, the lower viscera to about 5 inches.

#### THE REFLEX POSTURAL MECHANISM OF THE BELLY WALL.

Now, as is well known, when a living subject raises his body to the sitting or standing posture the upper viscera do not drop more than a half or three-quarters of an inch; the ligaments and mesenteries can therefore take no part in sustaining the viscera. The supporting structures are the muscles of the belly wall; particularly is the transversalis muscle important in this respect; it is a living belt which girds the loins. The moment we assume a sitting or standing posture there is set going a reflex mechanism which throws the muscles of the belly wall into a state of postural tone. François-Franck noted that when a dog was chlorotone, formed in the upright position tone departed from the muscles of the belly wall and the viscera sagged. When the posterior roots of the abdominal spinal nerves are cut, or, as Sherrington has demonstrated, when the afferent nerves from the viscera are severed, the abdominal musculature loses its postural tone. Surgeons are well aware that dragging on a mesentery or a ligament in an imperfectly anaesthetized patient gives rise to a dragging pain and to nausea. At the roots of the peritoneum has a rich supply of sensory nerves. The roots of mesenteries and within them are numerous Pacinian-like corpuscles. Very probably the afferent stimuli which set the reflex postural mechanism into operation arise from some or all of these sensory terminals. Possibly, too, the mechanism may require the accessory action of one or more hormone substances. It is sufficient for our present purpose to realize that the assumption of the orthograde posture demanded an elaboration of the mechanism of visceral support. Under modern conditions of life, this postural mechanism of man's body is particularly liable to break down. The cause of this breakdown we do not know, but all available evidence points to its being connected with errors in feeding and living rather than with any imperfection in Nature's evolutionary workmanship.

#### THE FUNCTION OF MESENTERIES AND OF VISCERAL LIGAMENTS.

If, as I have stated, mesenteries and visceral ligaments do not suspend the abdominal organs, then what are they for? If they do not serve the purpose of support, why is it that as we pass from the higher pronograde apes to the lower orthograde apes the areas of visceral fixation become much more extensive and closer? Then, again, as we pass from the gibbon to the large anthropoid apes we note that the

process of adhesion has extended, and reaches its farthest point in the human body. There cannot be a shadow of doubt that the degree of peritoneal fixation keeps step with the degree of adaptation of the body to the erect posture. The evolution of the maintenance of posture Nature never uses ligaments; it is always muscle, striped or unstriped, she employs for this purpose. I know of only one exception, and that is where yellow elastic tissue is employed between the laminae of vertebrae and in the subcutaneous tissue in the ventral wall of pronograde animals. This is into action when the muscular supports . . . overcome or have broken down; ligaments are a second line of defence—the first line is always held by muscles. Hence it is that if the postural tone of the abdominal musculature is damaged then the mesenteries and visceral ligaments come into action; the dropped organs become supported or suspended by their attachments. Very probably Mr. H. Tyrrell Gray is right in ascribing certain symptoms and disorders of intestinal function to tension on the nerves lying within the mesenteries. The increased areas of visceral fixation to be seen in the bodies of orthograde primates, particularly in the human body, are not for the suspension of organs, but to limit their movements and prevent entanglements. For example, it is not uncommon to find in the human body that the mesentery of the "ileo-caecal loop" has not become adherent to the posterior wall of the abdomen, but has remained free as in pronograde apes. In such cases neither the caecum nor ileum falls below its usual level; what does often happen is that the unfixed condition of the ileo-caecal tract permits a freedom of movement which may end in the loop becoming twisted and the bowel acutely obstructed.

#### INTRA-ABDOMINAL STRESSES.

There is another line of evidence which helps us to understand why peritoneal fixation has assumed so extensive a development in the human body. We are apt to forget that the chief muscles of the belly wall, the two recti, the external obliques, and the internal obliques, are primarily muscles of the spine; they are the powerful postural antagonists of the spinal muscles thus form a great cylinder, within which is packed the column of abdominal contents. Thus the abdominal contents are subject to the compressive action of the cylinder of postural muscle. During violent muscular effort the intra-abdominal pressure will mount up to 100 or 150 mm. Hg. In pronograde apes we cannot conceive that such high pressures can arise; the postural musculature of their trunks uses both fore and hind limbs as bases of action. With the evolution and maintenance of the orthograde posture, the shortening of and extension of the thighs, the abdominal contents the loins and extension of the thighs, the abdominal contents became subjected to greater degrees of compression and displacement, but even in the great anthropoids the maintenance of posture does not fall entirely on the musculature of the abdominal walls; weight in the upright position is partially borne by the upper extremities. It was with the evolution of the plantigrade posture of the human body that the postural compression of the abdominal viscera reached its highest point. The arms no longer assisted in supporting the body; the reverse became the case—the erect trunk had to afford a firm basis of action for the arms. For this purpose the postural complex of muscles which surround and enclose the abdominal cavity is called continuously into action. They tend to compress and displace the contents of the abdomen, and hence the human posture demands the most extensive system of visceral attachment.

It has also to be remembered that the upper viscera of the abdomen move with the respiratory tide. They must be fixed and shaped so that they may respond to all movements of the diaphragm and changes in shape of the thorax. The respiratory factor has to be kept in mind when we seek to explain the altered fixation of the abdominal viscera which occurred with the evolution of the orthograde posture.

#### TRANSFORMATION OF THE ABDOMINAL CAVITY.

Thus we see that the evolution of the orthograde posture was attended by a revolution in the attachment of the abdominal viscera and by an elaboration of the muscular mechanisms which keep the trunk erect and support the contents of the abdomen. Then, too, came a transformation in the shape of the abdominal cavity and a remodeling of such solid viscera as the liver and spleen. Everyone is familiar with the long loins of the common monkey and the keel-like form given to the hinder part of their bodies.

their usual pronograde or "four-footed" mode of progression the chest is more ventral in position than the flanks; hence the abdominal viscera tend to sag against the diaphragm. The iliac part of their pelvis is long, narrow, and situated dorsally, thus permitting the ventral musculature to exert an unfettered control over the contents in the hinder part of the abdomen. That part of their abdominal cavity which lies within the wings of the thorax is deep from back to front, but relatively narrow from side to side. We have seen that with the evolution of the orthograde posture the loins became shortened by the addition first of one lumbar vertebra to the sacrum, then of another. The dorsal wall of the abdomen was thus curtailed; so too were the abdominal aorta and the dorsal attachment of the mesentery. Attention has already been drawn to the widening of the orthograde trunk and to the flattening of its dorsal and ventral surfaces; the abdominal cavity necessarily underwent a corresponding change in shape: the domes of the diaphragm became wider and more capacious. A feature which is particularly worthy of note was the increased protrusion of the bodies of the vertebrae within the cavities of the thorax and abdomen. This vertebral protrusion led to a deepening of the hypocondriac recess which lies on each side of the vertebral column. In man, particularly after the lumbar curvature is fully developed, these recesses become deep and capacious. With the deepening of the recesses the viscera which lie within them, especially the kidneys, become withdrawn from direct muscular support, and hence are particularly liable to displacement. These changes in the shape of the abdominal cavity, which became more marked with each succeeding phase in the evolution of the orthograde posture, necessarily affected the form of the contained viscera and their mode of fixation.

#### THE EVOLUTIONARY RÔLE OF PERITONEAL ADHESIONS.

Having thus sketched in outline the chief changes which overtook the abdominal wall during the evolution of the upright body I now turn to note the postural adaptations to be recognized in the contained viscera. It is impossible in the course of a single lecture to deal with the matter fully; I shall restrict myself to one or two of the more significant changes, particularly those which have been brought about by a more extensive peritoneal adhesion of the viscera.

In the lowest and oldest primates known, as in the more recent and more highly specialized, the alimentary tract, from oesophagus to anus, falls into four natural sections or loops. These are: (1) the gastric loop, (2) the duodenal, (3) the ileo-colic, (4) the recto-colic. In the lowest primates these four loops are attached to the median line of the dorsal wall of the abdominal cavity by a continuous peritoneal sheet—the common mesentery. Even in this earliest of stages the gastric loop is seen to have undergone a rotation and its mesentery has become ballooned out to form a great omental sac—an occurrence which shows us that mesenteries are more than mere ligaments and that peritoneum is much more than a passive lining for the abdominal cavity. Even among pronograde monkeys the mesentery of the duodenal loop and the omental sac show various degrees of adhesion to the posterior wall of the abdomen. In the pronograde monkeys of the old world adhesions have already become extensive. The duodenum and pancreas have become sealed to the posterior wall of the abdomen. The rotation of the ileo-colic loop is now so complete that the proximal part of the colon falls into the right lumbar region in front of the duodenum. In the duodenal or right lumbar area an interesting complex of peritoneal adhesions is formed, chiefly out of the right extremity of the omental sac, which is attached to the pyloric end of the stomach and commencement of the duodenum. The fringes of the right end of the omentum have become plastic and adhesive in nature; they help to bind the colon to the right lumbar region and represent the initial stage in the evolution of the so-called Jacksonian membrane. In the old-world monkeys, too, is to be seen the first stage in the adhesion of the mesentery of the small bowel and transverse mesocolon—which collectively represent the common mesentery of the ileo-colon. The area of adhesion is restricted to the neighbourhood of the "root" of the mesentery. The mesentery of the distal part of the colon retains its primitive median attachment.

Then, when we pass from the highest of the pronograde apes to the lowest orthograde form represented by the gibbon, we find the process of peritoneal adhesion has proceeded apace. The omental sac has not only become adherent to the posterior abdominal wall but has become fused with the mesentery of the transverse segment of the

colon. Its right or hepatic extremity forms adhesive colic bonds in the loin, while its left or splenic extremity does the same in the left hypocondrium. The spleen has become adherent over the left kidney. The posterior aspects of both oesophageal and pyloric ends of the stomach have become more adherent. The fixation of the mesentery of the ileo-colon, which has reached only an initial stage in old-world monkeys, has become more extensive in the gibbon, but the extremity of the loop, including the terminal part of the small intestine and the beginning of the large intestine, is still free. It is in the gibbon we see the first stage in the process of sealing down the mesentery of the distal segment of the colon. The mesentery attached to the splenic flexure becomes fixed to the posterior wall of the abdomen, while the mesentery of the descending and sigmoid colons remains almost as free as in pronograde apes. In the great anthropoid apes we see a stage of adhesion which takes us almost to the extent seen in the human body. The colic adhesions developed out of the omental extremities at the hepatic and splenic flexures have become particularly abundant. The posterior aspect of ileo-colic mesentery has become adherent almost to the termination of the ileum. The mesentery of the descending colon has become sealed down to the left lumbar region, and the root of the meso-sigmoid shows signs of wider attachment. The human is but a slight exaggeration of the anthropoid stage.

Thus in the degrees to which the viscera are bound to the abdominal wall by a process of adhesion we have a complete series of evolutionary stages leading from the lowest stage seen in pronograde monkey to the stage seen in the highest orthograde primate—man. Nature has used the process of peritoneal adhesion as part of her evolutionary machinery. That she has done so is made manifest by the recapitulation of the evolutionary series in the developing abdominal system of the human foetus. It is but seldom that the developmental processes of the human body recapitulate evolutionary history with any degree of clearness; but in the development of the mesenteric adhesions I think there can be no doubt evolutionary history is repeated.

#### HOW DO POSTURAL ADAPTATIONS OF THE PERITONEUM ARISE?

Long ago Sir William Arbuthnot Lane recognized that there was a connexion between posture and the formation of peritoneal adhesions. He spoke of such adhesions as being "crystallizations in the lines of force." This explanation may be true, but it does not help us to understand how adhesions occur in the foetus. A more profitable approach to the problem is the recognition that all the cells which line the peritoneum have in them, as an inherent quality, the power to form adhesions; that power becomes manifest whenever an irritant or toxic substance is applied to them. We must suppose, then, that this quality which is inherent in living peritoneal cells can be evoked somehow during embryonic and foetal life. The stimulus, whatever its nature may be, acts in a controlled manner on a sequence of definite areas, and produces a series of adaptational adhesions which serve to meet a need of the body.

#### THE DESCENT OF THE TESTES.

To understand the protean and plastic qualities of developing peritoneum one has only to recall Hunter's account of the nature of the process which brings about descent of the testicle. The gubernaculum testis may be described as a peritoneal growth plug; it is a cellular mass formed out of peritoneum and subperitoneal elements. The gubernaculum as it approaches the groin brings about a proliferation and an evagination of all the strata of the inguinal wall. The descent of the testicle, whatever the physiological reason for it may be, is not a more obscure or a more wonderful process than the formation of a peritoneal adhesion. Both are manifestations of developmental or growth qualities inherent in the lining membrane of the abdomen. Hunter has been criticized for using the phrase "stimulus of perfection" to designate the cause which set the machinery of descent in motion. If we translate Hunter's phrase "stimulus of perfection" to mean a hormone substance which is produced by a normal developing testis, we are only giving his language and his explanation a modern garb.

One other instance I may cite to illustrate the active qualities of developing peritoneum. In all forms of primates the ileo-colic loop of intestine undergoes a rotation during development, the rotation bringing the beginning of the colon into the right lumbar region. In the human embryo the

rotation of this loop takes place as it is withdrawn from the umbilical sac at the end of the second month of foetal life. My friend Professor J. E. S. Frazer has made a very thorough study of the mechanism<sup>1</sup> which brings about the turning over of the colic end of the loop. From his observations there can be no doubt, I think, that the retraction of the loop from the umbilicus and its rotation are produced by certain growth bands—or rather retraction bands—which develop along certain sectors of the mesentery of the loop. The rotation of the ileo-colic intestinal loop is a growth phenomenon not unlike in nature to that which we see manifested in the descent of the testicle.

It would take us too far afield in this lecture to discuss the modifications undergone by the liver and stomach with the evolution of the orthograde posture. I shall content myself, so far as the liver is concerned, by drawing attention to the fact that the change in posture was attended, as in the adjacent right lung, by the disappearance of the large caudate lobe. In the human liver a vestige of the caudate lobe is always present, showing that man has come of an ancestry which was pronograde in posture. As for the stomach, I shall merely mention that in the human child this organ is shaped as in anthropoid apes, and occupies the same high horizontal position. At what period of adolescence the infantile form is replaced by the elongated, vertically placed stomach of adult life has yet to be ascertained, but the change in shape must certainly be attributed to man's erect posture.

# A NOTE ON THE NATURE OF THE SUGAR IN BLOOD.

338

J. A. HEWITT, Ph.D., B.Sc.

(From the Department of Physiology, King's College, University of London.)

The recent important advances made by Irvine and his co-workers as to the constitution of the carbohydrates lend themselves admirably to speculation regarding the possible function and significance of the now definitely established "γ" sugars in the metabolic processes of both plant and animal.

Direct evidence of the formation of these reactive isomerides in biological reactions was lacking until the present author and Pryde (Hewitt and Pryde, 1920) showed with some certainty that  $\gamma$  glucose and  $\gamma$  fructose are formed and can be detected when the stable  $\alpha$  and  $\beta$  isomerides are in contact with living intact intestine. We contented ourselves with recording the experimental facts, and refrained from discussing any theoretical extension of the work, attractive and obvious as such discussion was, beyond saying, "The possibility thus suggests itself that in the rapid transformation of carbohydrate in living tissues  $\gamma$  sugars may play an important if not an essential part." Later Hewitt and de Souza (1921) remarked with similar reserve on this question, "It may be presumed on *a priori* grounds that a structural change of the nature referred to has some fundamental reason."

Since the communications mentioned above, three publications have appeared in which Hewitt and Pryde's results are quoted in some detail, and in each case are accepted, extended, and employed for the formulation of a theory as to the causation of diabetes mellitus.

Before discussing the evidence adduced in these researches, on which this theory is based, it is perhaps advisable to emphasize the extreme difficulty that exists in interpreting results in this field of work. Most, if not all, of the biochemical data are and must necessarily be indirect; consideration is required, therefore, both in devising experiments and in drawing conclusions therefrom if advance is to be made without confusion avoided.

workmanship. The option avoided. The properties of  $\gamma$  sugars must be deduced from the LIGAM deal in discussing their formation and erroneous reactions at the processes, it might be well to the known grounds of alosenteries, it might be well to the final grounds of alosenteries, it might be well to the existence in metabolic processes, it might be well to the relevant salient features of such sugars as the study of their monosaccharide derivatives.

2. Two  $\gamma$  isomerides exist in the case of each hexene, analogous in their mutual relations to the  $\alpha$  and  $\beta$  modifications. Possibly these  $\gamma$  isomers undergo mutarotation *inter se* as well as stereochemical change to the stable form; the last reaction is undoubtedly extremely rapid.

3. The chemical reactivity of  $\gamma$  sugars is very great, and condensation with alcohols to form glucosides takes place rapidly at room temperature. Fehling's solution is reduced in the cold, they unite readily with oxygen to form explosives, which in turn easily undergo disaccharide formation.

4. Unsubstituted  $\gamma$  sugars show marked instability to traces of acid or alkali.

Such properties manifestly render detection a matter of difficulty, which is further increased when it is remembered that one isomeride of  $\gamma$  glucose is strongly laevo-rotatory, while  $\beta$  glucose is only feebly dextro-rotatory. Apart from isolation of derivatives of these sugars, identification in biological reactions depends on polarimetric determination of optical behaviour and on the reduction of alkaline potassium permanganate.

Polarimetric evidence alone, therefore, must exclude rigorously the presence of  $\beta$  glucose in amount greater than that found normally in aqueous glucose solution in equilibrium. This is referred to in further detail below. The dangers attending the use of permanganate with biological material are obvious; the employment of this reagent requires careful control, and at best can be applied only with extreme caution to such complex solutions as blood or urine.

In my opinion the evidence on which Cooper and Walker (1922), and Winter and Smith (1922) base their theory is insufficient when the essential properties of  $\gamma$  sugars are considered. Cooper and Walker separated blood from a hexose solution (glucose or fructose) by a dialysing membrane and examined, with negative results, the sugar polarimetrically and with permanganate. Several objections can be raised to this technique:

(a) The blood was extravascular and, having undergone at least preliminary stages towards coagulation, was not normal. If it were citrated or oxalated (this is not stated) its condition is possibly still more abnormal.

(b) Owing to physical properties no enzyme could pass from the blood inside the dialyser to the sugar outside. Before any action could take place the hexose substrate would have to pass through the membrane. Unless preferential dialysis of one of the  $\alpha$  or  $\beta$  isomerides had occurred no change in the specific rotation would be found, if the sugars were in equilibrium at the beginning of the experiment.

(c) As the concentration of hexose outside the dialyser was greater than within, no transference of sugar from within outwards would be produced. The value, therefore, of examining the sugar outside does not seem apparent.

(d) Inherent dangers in the use of potassium permanganate exist; as, however, no reduction took place, the inference is perhaps not without reason that no dialysis of any component had occurred in either direction, for the various extractives of blood are far from inactive as regards this reagent, and owing to relative concentration would be removed from the blood inside to the solution which was tested.

Negative results obtained from experiments based on such technique do not warrant the superstructure of theory erected thereon. Hewitt and de Souza (loc. cit.) had previously clearly demonstrated what Cooper and Walker attempted. Kunitz and Smith (1922), in a more elaborate study, reached the same conclusion. The sugar is  $\gamma$  glucose, and

Winter and Smith (1922), in a more elaborate study, reached the conclusion that the normal blood sugar is  $\gamma$  glucose, and that an enzyme exists (not in the blood) for effecting the transformation of the stable butylene oxide glucoses into  $\gamma$  glucose.

I agree that no such enzyme can be demonstrated in the blood (see Hewitt and de Souza, loc. cit.), but am of opinion that objections may be raised both to Winter and Smith's view of blood sugar and to the experimental evidence on which they found their theory.

Dealing with the technique employed by these authors it is to be observed that in the course of preparing their final filtrate for polarimetric examination the following manipulative operations, among others, were performed: (1) precipitation with tungstic acid; (2) heating to 45° C.; (3) addition of ethyl and propyl alcohol and contact with these alcohols for twenty minutes at moderate temperature; (4) concentration.

\* Possibility of preferential dialysis was apparently not excluded. It may be stated, however, that alteration of optical values due to it - not be detected. (Unpublished experiments.)

their usual pronograde or "four-footed" mode of progression the chest is more ventral in position than the flanks; hence the abdominal viscera tend to sag against the diaphragm. The iliac part of their pelvis is long, narrow, and situated dorsally, thus permitting the ventral musculature to exert an unfettered control over the contents in the hinder part of the abdomen. That part of their abdominal cavity which lies within the wings of the thorax is deep from back to front, but relatively narrow from side to side. We have seen that with the evolution of the orthograde posture the loins became shortened by the addition first of one lumbar vertebra to the sacrum, then of another. The dorsal wall of the abdomen was thus curtailed; so too were the abdominal aorta and the dorsal attachment of the mesentery. Attention has already been drawn to the widening of the orthograde trunk and to the flattening of its dorsal and ventral surfaces; the abdominal cavity necessarily underwent a corresponding change in shape: the domes of the diaphragm became wider and more capacious. A feature which is particularly worthy of note was the increased protrusion of the bodies of the vertebrae within the cavities of the thorax and abdomen. This vertebral protrusion led to a deepening of the hypochondriac recess which lies on each side of the vertebral column. In man, particularly after the lumbar curvature is fully developed, these recesses become deep and capacious. With the deepening of the recesses the viscera which lie within them, especially the kidneys, become withdrawn from direct muscular support, and hence are particularly liable to displacement. These changes in the shape of the abdominal cavity, which became more marked with each succeeding phase in the evolution of the orthograde posture, necessarily affected the form of the contained viscera and their mode of fixation.

#### THE EVOLUTIONARY RÔLE OF PERITONEAL ADHESIONS.

Having thus sketched in outline the chief changes which overtook the abdominal wall during the evolution of the upright body I now turn to note the postural adaptations to be recognized in the contained viscera. It is impossible in the course of a single lecture to deal with the matter fully; I shall restrict myself to one or two of the more significant changes, particularly those which have been brought about by a more extensive peritoneal adhesion of the viscera.

In the lowest and oldest primates known, as in the more recent and more highly specialized, the alimentary tract, from oesophagus to anus, falls into four natural sections or loops. These are: (1) the gastric loop, (2) the duodenal, (3) the ileo-colic, (4) the recto-colic. In the lowest primates these four loops are attached to the median line of the dorsal wall of the abdominal cavity by a continuous peritoneal sheet—the common mesentery. Even in this earliest of stages the gastric loop is seen to have undergone a rotation and its mesentery has become ballooned out to form a great omental sac—an occurrence which shows us that mesenteries are more than mere ligaments and that peritoneum is much more than a passive lining for the abdominal cavity. Even among pronograde monkeys the mesentery of the duodenal loop and the omental sac show various degrees of adhesion to the posterior wall of the abdomen. In the pronograde monkeys of the old world adhesions have already become extensive. The duodenum and pancreas have become sealed to the posterior wall of the abdomen. The rotation of the ileo-colic loop is now so complete that the proximal part of the colon falls into the right lumbar region in front of the duodenum. In the duodenal or right lumbar area an interesting complex of peritoneal adhesions is formed, chiefly attached to the pyloric end of the omental sac, which is vent of the duodenum. The fringes of the right end of the omentum have become plastic and adhesive in nature; they help to bind the colon to the right lumbar region and represent the initial stage in the evolution of the so-called Jacksonian membrane. In the old-world monkeys, too, is to be seen the first stage in the adhesion of the mesentery of the small bowel and transverse mesocolon—which collectively represent the common mesentery of the ileo-colon. The area of adhesion is restricted to the neighbourhood of the "root" of the mesentery. The mesentery of the distal part of the colon retains its primitive median attachment.

Then, when we pass from the highest of the pronograde apes to the lowest orthograde form represented by the gibbon, we find the process of peritoneal adhesion has proceeded apace. The omental sac has not only become adherent to the posterior abdominal wall but has become fused with the mesentery of the transverse segment of the

colon. Its right or hepatic extremity forms adhesive colic bonds in the loin, while its left or splenic extremity does the same in the left hypochondrium. The spleen has become adherent over the left kidney. The posterior aspects of both oesophageal and pyloric ends of the stomach have become more adherent. The fixation of the mesentery of the ileo-colon, which has reached only an initial stage in old world monkeys, has become more extensive in the gibbon, but the extremity of the loop, including the terminal part of the small intestine and the beginning of the large intestine, is still free. It is in the gibbon we see the first stage in the process of sealing down the mesentery of the distal segment of the colon. The mesentery attached to the splenic flexure becomes fixed to the posterior wall of the abdomen, while the mesentery of the descending and sigmoid colons remains almost as free as in pronograde apes. In the great anthropoid apes we see a stage of adhesion which takes us almost to the extent seen in the human body. The colic adhesions developed out of the omental extremities at the hepatic and splenic flexures have become particularly abundant. The posterior aspect of ileo-colic mesentery has become adherent almost to the termination of the ileum. The mesentery of the descending colon has become sealed down to the left lumbar region, and the root of the meso-sigmoid shows signs of wider attachment. The human is but a slight exaggeration of the anthropoid stage.

Thus in the degrees to which the viscera are bound to the abdominal wall by a process of adhesion we have a complete series of evolutionary stages leading from the lowest stage seen in pronograde monkey to the stage seen in the highest orthograde primate—man. Nature has used the process of peritoneal adhesion as part of her evolutionary machinery. That she has done so is made manifest by the recapitulation of the evolutionary series in the developing abdominal system of the human foetus. It is but seldom that the developmental processes of the human body recapitulate evolutionary history with any degree of clearness; but in the development of the mesenteric adhesions I think there can be no doubt evolutionary history is repeated.

#### HOW DO POSTURAL ADAPTATIONS OF THE PERITONEUM ARISE?

Long ago Sir William Arbuthnot Lane recognized that there was a connexion between posture and the formation of peritoneal adhesions. He spoke of such adhesions as being "crystallizations in the lines of force." This explanation may be true, but it does not help us to understand how adhesions occur in the foetus. A more profitable approach to the problem is the recognition that all the cells which line the peritoneum have in them, as an inherent quality, the power to form adhesions; that power becomes manifest whenever an irritant or toxic substance is applied to them. We must suppose, then, that this quality which is inherent in living peritoneal cells can be evoked somehow during embryonic and foetal life. The stimulus, whatever its nature may be, acts in a controlled manner on a sequence of definite areas, and produces a series of adaptational adhesions which serve to meet a need of the body.

#### THE DESCENT OF THE TESTIS.

To understand the protean and plastic qualities of developing peritoneum one has only to recall Hunter's account of the nature of the process which brings about descent of the testicle. The gubernaculum testis may be described as a peritoneal growth plug; it is a cellular mass forced out of the peritoneum and antiperitoneal elements. The gubernaculum as it approaches the groin brings about a proliferation and evagination of all the strata of the inguinal wall. This it may be, is not a mere chance or a more wonderful process than the formation of a peritoneal adhesion. Both are in the lining membrane of the abdomen. Hunter criticized for using the phrase "descent" a case of this kind, in motion. If we translate Hunter's "descent" as "descent of the blood was made, section" to mean a homocarpous, we have seen four similar cases, in each of a normal developing testis, examined during life; in three the and his explanation a mystery.

One other instance I have present, and in one *Bacillus coli*. Qualities of developing peritoneum in the blood in cases in the ileo-colic loop of the development, the relative into the right lumbar.

rotation of this loop takes place as it is withdrawn from the umbilical sac at the end of the second month of foetal life. My friend Professor J. E. S. Frazer has made a very thorough study of the mechanism<sup>1</sup> which brings about the turning over of the colic end of the loop. From his observations there can be no doubt, I think, that the retraction of the loop from the umbilicus and its rotation are produced by certain growth bands—or rather retraction bands—which develop along certain sectors of the mesentery of the loop. The rotation of the ileo-colic intestinal loop is a growth phenomenon not unlike in nature to that which we see manifested in the descent of the testicle.

It would take us too far afield in this lecture to discuss the modifications undergone by the liver and stomach with the evolution of the orthograde posture. I shall content myself, so far as the liver is concerned, by drawing attention to the fact that the change in posture was attended, as in the adjacent right lung, by the disappearance of the large caudate lobe. In the human liver a vestige of the caudate lobe is always present, showing that man has come of an ancestry which was pronograde in posture. As for the stomach, I shall merely mention that in the human child this organ is shaped as in anthropoid apes, and occupies the same high horizontal position. At what period of adolescence the infantile form is replaced by the elongated, vertically placed stomach of adult life has yet to be ascertained, but the change in shape must certainly be attributed to man's erect posture.

## A NOTE ON THE NATURE OF THE SUGAR IN BLOOD.

BY

J. A. HEWITT, Ph.D., B.Sc.

(From the Department of Physiology, King's College, University of London.)

THE recent important advances made by Irvine and his co-workers as to the constitution of the carbohydrates lend themselves admirably to speculation regarding the possible function and significance of the now definitely established "γ" sugars in the metabolic processes of both plant and animal.

Direct evidence of the formation of these reactive isomerides in biological reactions was lacking until the present author and Pryde (Hewitt and Pryde, 1920) showed with some certainty that γ glucose and γ fructose are formed and can be detected when the stable α and β isomerides are in contact with living intact intestine. We contented ourselves with recording the experimental facts, and refrained from discussing any theoretical extension of the work, attractive and obvious as such discussion was, beyond saying, "The possibility thus suggests itself that in the rapid transformation of carbohydrate in living tissues γ sugars may play an important if not an essential part." Later Hewitt and de Souza (1921) remarked with similar reserve on this question, "It may be presumed on *a priori* grounds that a structural change of the nature referred to has some fundamental reason."

Since the communications mentioned above, three publications have appeared in which Hewitt and Pryde's results are quoted in some detail, and in each case are accepted, extended, and employed for the formulation of a theory as to the causation of diabetes mellitus.

Before discussing the evidence adduced in these researches, on which this theory is based, it is perhaps advisable to emphasize the extreme difficulty that exists in interpreting results in this field of work. Most, if not all, of the biochemical data are and must necessarily be indirect; consideration is required, therefore, both in devising experiments and in drawing conclusions therefrom if advance is to be made.

THE FUNCTION OF MESAD properties of γ sugars must be considered in discussing their formation.

If, as I have concluded, mesenteric processes, it might be well to consider the erroneous reactions of such sugars as γ glucose and γ fructose in the metabolic processes of the body. It is generally accepted for the

2. Two γ isomerides exist in the case of each hexose, analogous in their mutual relations to the α and β modifications. Possibly these γ isomerides undergo mutarotation *inter se* as well as stereochemical change to the stable form; the last reaction is undoubtedly extremely rapid.

3. The chemical reactivity of γ sugars is very great, and condensation with alcohols to form glucosides takes place rapidly at room temperature. Fehling's solution is reduced in the cold, they unite readily with oxygen to form oxy-compounds, which in turn easily undergo disaccharide formation.

4. Unsubstituted γ sugars show marked instability to traces of acid or alkali.

Such properties manifestly render detection a matter of difficulty, which is further increased when it is remembered that one isomeride of γ glucose is strongly laevo-rotatory, while β glucose is only feebly dextro-rotatory. Apart from isolation of derivatives of these sugars, identification in biological reactions depends on polarimetric determination of optical behaviour and on the reduction of alkaline potassium permanganate.

Polarimetric evidence alone, therefore, must exclude rigorously the presence of β glucose in amount greater than that found normally in aqueous glucose solution in equilibrium. This is referred to in further detail below. The dangers attending the use of permanganate with biological material are obvious; the employment of this reagent requires careful control, and at best can be applied only with extreme caution to such complex solutions as blood or urine.

In my opinion the evidence on which Cooper and Walker (1922), and Winter and Smith (1922) base their theory is insufficient when the essential properties of γ sugars are considered. Cooper and Walker separated blood from a hexose solution (glucose or fructose) by a dialysing membrane and examined, with negative results, the sugar polarimetrically and with permanganate. Several objections can be raised to this technique:

(a) The blood was extravascular and, having undergone at least preliminary stages towards coagulation, was not normal. If it were citrated or oxalated (this is not stated) its condition is possibly still more abnormal.

(b) Owing to physical properties no enzyme could pass from the blood inside the dialyser to the sugar outside. Before any action could take place the hexose substrate would have to pass through the membrane. Unless preferential dialysis of one of the α or β isomerides had occurred no change in the specific rotation would be found, if the sugars were in equilibrium at the beginning of the experiment.

(c) As the concentration of hexose outside the dialyser was greater than within, no transference of sugar from within outwards would be produced. The value, therefore, of examining the sugar outside does not seem apparent.

(d) Inherent dangers in the use of potassium permanganate exist; as, however, no reduction took place, the inference is perhaps not without reason that no dialysis of any component had occurred in either direction, for the various extractives of blood are far from inactive as regards this reagent, and owing to relative concentration would be removed from the blood inside to the solution which was tested.

Negative results obtained from experiments based on such technique do not warrant the superstructure of theory erected thereon. Hewitt and de Souza (*loc. cit.*) had previously clearly demonstrated what Cooper and Walker attempted.

Winter and Smith (1922), in a more elaborate study, reached the conclusion that the normal blood sugar is γ glucose, and that an enzyme exists (not in the blood) for effecting the transformation of the stable butylene oxide glucoses into γ glucose.

I agree that no such enzyme can be demonstrated in the blood (see Hewitt and de Souza, *loc. cit.*), but am of opinion that objections may be raised both to Winter and Smith's view of blood sugar and to the experimental evidence on which they found their theory.

Dealing with the technique employed by these authors it is to be observed that in the course of preparing their final filtrate for polarimetric examination the following manipulative operations, among others, were performed: (1) precipitation with tungstic acid; (2) heating to 45°C.; (3) addition of ethyl and propyl alcohol and contact with these alcohols for twenty minutes at moderate temperature; (4) concentration.

\* Possibility of preferential dialysis was apparently not considered. It may be stated, however, that alteration of optical values due to

almost to dryness; and (5) solution in water for at least three days.

Consideration of the known reactions of  $\gamma$  glucose renders it unlikely that such a labile substance would remain unaffected by tungstic acid. Since no strict proof is available as to the action of this reagent on  $\gamma$  sugars this point perhaps should not be stressed. The second operation, heating to 40° C., is one which undoubtedly hastens the mutarotation of any system of isomeric sugars not in equilibrium. The third operation, treatment with alcohol, appears to be one which would rule out all possibility of obtaining the free reactive sugar. I need only refer to the extraordinary capacity which these sugars possess for undergoing glucoside formation with alcohols, or for condensation with acetone. Finally, the acidity of the filtrate is in itself no small objection to the conclusions reached.

It is thus seen that the technique adopted by Winter and Smith is in its essentials one calculated to remove effectively any  $\gamma$  glucose which may have been originally present, and it is difficult to see how the optical observations of the filtrate throw any light on the condition of the original blood sugar.

Dealing next with the times taken to attain a constant optical value, it may be noted that final equilibrium was not reached till after two to four days. It need only be pointed out that such a slow reaction is not a feature of  $\gamma$  sugars or of their mutarotating derivatives. It is regrettable that more complete data are not given, as it is impossible to analyse as fully as might be desired the optical behaviour of the dilute filtrate with a view to interpreting the nature or course of the reaction. It does not appear, however, that the authors have excluded the presence (or formation) of  $\beta$  glucose, with specific rotation +19°, in amount greater than that in aqueous glucose solution in equilibrium. Similarly with diabetic blood where the optical change is a downward mutarotation, the possibility of the presence of excess of  $\alpha$  glucose (specific rotation +110°) must be admitted. So far as can be judged, the optical variations observed do not lie outside values arising from temporary disturbance of the equilibrium between the  $\alpha$  and  $\beta$  butylene oxide glucoses.

No mention is made of precautions to ensure sterility of the sugar solution kept for four days. Non-sterility of the final material obtained—containing, presumably, substances susceptible to bacterial action in addition to glucose—might well account for optical changes. The action on permanganate of the filtrate, fresh and after standing for several days, is similarly not conclusive. Relatively simple oxidative changes, or even saturation of unsaturated compounds, might account for the phenomena observed. This apparently was not controlled. Winter and Smith (1923) state also "the sugar" (of normal blood—that is,  $\gamma$  glucose) "gives an osazone with the same crystalline form and melting point as that of glucosazone." In this connexion Irvine, Fyfe, and Hogg (1915) have shown that  $\gamma$  glucose "reacts with phenylhydrazine and acetic acid, but is thereby resinified, and, in addition, a definite anilide, or other crystalline derivative, could not be obtained." This observation hardly supports the presence of  $\gamma$  glucose in the blood examined by Winter and Smith.

The experiments of Winter and Smith cannot be regarded as crucial, and the question demands rigorous investigation before the existence of  $\gamma$  glucose in more than normal traces can be accepted as the circulating sugar of blood.

In addition it may be pointed out that Winter and Smith's suggestion as to the non-formation of  $\gamma$  glucose in the diabetic does not in any way account for the downward change in optical values found in blood in this pathological state. If their conclusions were sound the optical value of diabetic blood should not vary on standing under aseptic conditions as there could be no transformation from one isomeride to another and the relation of the optical value to the copper value should be a constant throughout. Evidence from pathological conditions also fails to support the main thesis.

The experimental evidence brought by these authors is not, however, such as lends itself to profitable discussion, but among the many possible complicating factors may be indicated the opposed rotations of the conjugated glycuronates and of the free acid.

While admitting, in the absence of any proof, that the reactive forms of sugars are in all probability of fundamental metabolic importance, it is perhaps not necessary to assume that the normal blood sugar is this modification. If the reserve carbohydrate of plants and animals be considered, in no case (except inulin) is it found that  $\gamma$  sugars are present

in combination and are liberated on hydrolysis. Starch, glycogen, and cellulose are condensation products of stable butylene oxide glucose. (Irvine, 1922; Irvine and Macdonald, 1922; Irvine, Denham, and Hirst, 1922.)

Inulin is exceptional, and shares with cellulose the distinction of being of but small value to man as a source of carbohydrate. Sucrose appears to be the only foodstuff in which a  $\gamma$  sugar is available as such for absorption, and it will be noted that it has to undergo hydrolysis before the  $\gamma$  fructose is liberated. No form of reserve carbohydrate as such behaves as a  $\gamma$  sugar.

The sugar of blood cannot but be regarded as a store of carbohydrate ready for consumption at short notice, and following the analogy of the known condition of other reserve carbohydrates one would not be surprised to find the simple monosaccharide to be the stable butylene oxide modification. Furthermore, if one considers the extraordinary chemical reactivity of  $\gamma$  sugars it is but reasonable to suppose that they would not be in this condition in blood.

It may well be that only when required for oxidative processes would the stable form undergo stereochemical change into the reactive modification, and free  $\gamma$  glucose might have but a transient existence, and might almost be regarded as an intermediate product in the katabolism of glucose. Evidence of this will possibly be by no means easy to obtain. In this connexion also it may be noted that Dakin (1922), after reviewing the literature on carbohydrate metabolism, concludes: "Active glucose metabolism only seems to occur in the presence of living and surviving cells."

Until evidence is brought that  $\gamma$  glucose does exist as the sugar of blood and does not exist in diabetic blood, no theory of diabetes can be formulated as to the relation of these sugars to this pathological condition. Observations are in progress on the optical behaviour of equilibrated solutions of sugars in the intestine of the diabetic organism. It is hoped in this way to obtain a decision on this point.

#### Summary.

1. No evidence exists that  $\gamma$  glucose is a component of normal blood.
2. Theories of diabetes mellitus demanding the presence of  $\gamma$  glucose in normal blood are without experimental foundation.
3. Formation of  $\gamma$  glucose in carbohydrate metabolism may take place as and when required and the active modification may possibly have no more than a transitory existence.

## ON SEPTICAEMIC INFECTION FOLLOWING OPERATIONS FOR APPENDICITIS.

### A PROPHYLACTIC SERUM.

BY

HERBERT H. BROWN, O.B.E., M.D., F.R.C.S.,  
 CONSULTING SURGEON TO THE EAST SUFFOLK HOSPITAL, IPSWICH.

I HAVE drawn attention in previous communications<sup>1</sup> to a train of symptoms which sometimes follows operations for appendicitis in children, if performed from the third to the sixth day from the commencement of the attack, and always leads to a fatal termination within about forty-eight hours; and I gave reasons for my belief that these symptoms indicated a septic infection of the blood taking place at the time of operation.

In the more recent paper I described a case of this kind, in which a bacteriological examination of the blood was made, and the *Streptococcus faecalis* was found in pure culture. Since that date I have seen four similar cases, in each of which the blood was examined during life; in three the *S. faecalis* was found to be present, and in one *Bacillus coli*. I have not found these organisms in the blood in cases in which these symptoms had not made their appearance.

*Symptoms of Septicaemic Infection.*

The train of events is as follows: The operation is performed on a child on the third, fourth, or fifth day. In some cases nothing but drainage of an abscess is undertaken with as little disturbance as possible; in others the appendix is removed; but in all the infection has already spread beyond the appendix, causing inflammation of the surrounding tissues or actual pus formation.

For the first thirty-six hours, or perhaps a little longer, the child seems to be doing well and all the symptoms are satisfactory. The temperature is often normal, pulse slower than before the operation, abdomen flat, no pain or vomiting. The child usually sleeps well for the first night, and everything appears to be satisfactory. Then a rapid and almost sudden change for the worse takes place; the face becomes pale, the pulse rate commences to rise, the temperature is usually subnormal, the child becomes restless and irritable (this is a very marked feature), then drowsiness with restless intervals supervenes, and an occasional shrill "meningeal" cry is uttered which is very characteristic; in fact, all the symptoms are of a cerebral type—the pupils become dilated; coma with a rapidly rising temperature is followed by death, generally within thirty-six hours of the onset of the symptoms. The clinical picture is a very tragic and striking one, and in each case which I have seen in my own practice or that of others the symptoms have been practically identical.

*Post mortem* nothing is found to account for death. There is no peritonitis, nothing abnormal in the site of operation, no sign of meningitis.

When my attention was first drawn to these cases, about thirteen years ago, I gave what I believed to be the true explanation of them, and further experience has strongly confirmed that belief. It is well known that patients suffering from appendicitis, even after perforation and abscess formation has taken place, may recover without surgical interference: this was more often seen in former years before operations were as commonly undertaken as they are at present and the disease was spoken of as typhlitis or perityphlitis: the abscess perforated into a neighbouring viscus, generally the caecum, and the patient recovered. Operations, which were performed as a rule later than they are now, some time during the second week, when a large abscess was evident, were attended by little if any danger.

If the infection is very acute or the patient's natural resistance low, Nature unaided by the surgeon is defeated. The appendix wall sloughs and perforates into the general peritoneal cavity, causing a rapidly fatal peritonitis and toxæmia. Nature has had no time to mobilize her forces. But in other cases where the resistance is stronger or the virulence of infection less, and the poison is for a longer period confined to the appendix, toxins leaking through its wall set up inflammatory changes in the surrounding tissues, omentum, bowel, or parietal peritoneum. Before actual pus has been formed, a wall of plastic lymph has been thrown up, covering the surrounding inflamed tissues and shutting off the general cavity of the peritoneum, and at the same time sealing up the lymphatics and blood vessels in the inflamed tissues. It acts like the porcelain of a filter, allowing toxins to percolate through into the lymphatics and blood vessels but holding back the infective organisms—*B. coli* and streptococci. This is the first line of defence.

Its production gives time for the development of the second line, which I believe to be of very great importance—that is, the production of antibodies in the blood. The toxins soaking through the wall of lymph into the blood lead to the production of antibodies, which by the middle of the second week have produced a considerable degree of immunity. There is often at this time (if the patient has been allowed to reach this stage) a considerable improvement in the general condition—the temperature may fall to normal and the pulse rate diminish. The abscess, which is frequently a large one, may be opened without any danger, without even infecting the wound, which has been freely irrigated with stinking pus.

When an operation is performed during the middle of the first week the wall of lymph may be disturbed, or rubbed off, or may not have been properly formed, and a direct inoculation of infective material, containing *B. coli* or *S. faecalis*, into the blood stream may take place. This, after a short incubation period (twenty-four to thirty-six hours, or a little longer), is followed by the onset of symptoms due to septicaemic infection. If the operation is deferred to the second week the blood will have been rendered immune to this infection—the second line of defence will have had time to be mobilized, and these septicaemic symptoms do not appear.

If a case of appendicitis is seen early enough—during the first twenty-four hours—there is no question as to the proper treatment. The appendix should be removed at once. The

post-operative risk is practically nil, and no drainage is required. But if the case first comes to the surgeon at a later stage the right line of treatment is not so obvious; the dangerous period from the third to the sixth day of disease is present. It might be wiser to wait for several days until the abscess has reached a fair size and the blood has become relatively immune to infection before operating. But there are dangers and disadvantages in delay. The abscess might burst into the general peritoneal cavity. The child is in pain and distress, the parents are anxious and expecting immediate relief by the surgeon. Should the case end fatally after all, the surgeon will be blamed for his procrastination. It is difficult, even if he so wishes, for the surgeon to withhold his hand.

It occurred to me that it might be possible by injecting a prophylactic serum before and at the time of operation and shortly afterwards, to produce an immunity for the time which would prevent or largely minimize the danger of blood infection at the operation if performed during the dangerous period. I explained my views to Dr. Ledingham of the Lister Institute, who discussed the matter with Dr. MacConkey, the bacteriologist in charge of the serum department. Dr. MacConkey very kindly arranged to immunize a horse with cultures of *S. faecalis* and *B. coli* provided from cases of mine, and last March sent me a supply of serum. Unfortunately I have not been able to test the value of the serum as a prophylactic sufficiently, and as in the meantime I have retired from active work on the hospital staff my opportunities have been lessened. But the serum is still available, and I hope, with the aid of surgical colleagues, to be able to give it a full trial, and publish a further report.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## HYPEREMESIS GRAVIDARUM.

The following case presents certain features which appear worthy of record:

The patient, a young Jewish lady, had had three pregnancies terminated artificially on account of intractable hyperemesis. She was most anxious to have a child. She became pregnant towards the end of December, 1921, and vomiting began within a few days. She came under my care on January 3rd, 1922. Vomiting was persistent and salivation profuse. I began the line of treatment elaborated by Professor Harding of Toronto. I also administered peptone intramuscularly, having known a number of cases successfully treated by this method by a former partner, in one of these cases the uterus had been emptied twice on account of hyperemesis.

My patient was able to take no nourishment by the mouth except lactose. She improved steadily until on January 16th there was no vomiting and she partook of lemonade, bread-and-butter, and lettuce. Fruit and fish were soon added to the dietary. The condition remained satisfactory until February 14th, when bile was vomited and salivation became profuse. The bilious vomiting increased in frequency and amount, and on February 17th I called in a colleague who had attended her in two previous pregnancies. He expressed his disappointment at her excellent general condition. The patient continued with slight intermissions. On March 6th the nurse reported that there had been a slight vaginal discharge. This was brown in colour and odourless. The patient became somewhat restless, but the pulse rate was only slightly raised (90). On the following morning the condition was not improved and the pulse rate had risen to 110. I arranged a consultation with my colleague at the earliest possible moment. When we saw her the pulse rate was 130, and it was decided to empty the uterus, the patient, who was fully conscious, protesting vigorously. The operation was carried out under ether anaesthesia with all possible speed, continuous saline being administered. The heart failed rapidly and death ensued some hours later.

There were no foetal products recognizable in the uterine contents. Albumin was at no time present in the urine, and was aceto-acetic acid, but bile appeared in the last few days.

NORMAN WILSON, M.A., M.D., B.Ch. Cantab.

Port Elizabeth, South Africa.

## British Medical Association.

## CLINICAL AND SCIENTIFIC PROCEEDINGS.

## SIERRA LEONE BRANCH.

The second scientific meeting of this newly organized Branch of the British Medical Association was held at the office of the Director of Medical and Sanitary Services, Freetown, on January 26th, with the President, Professor B. BLACKLOCK, in the chair.

Dr. J. D. DIMOCK presented two cases of interest.

The first was a boy, aged 14 years, with a dental cyst; a brief dissertation on the pathology of the condition was given, and the proposed method of treatment outlined. The second was a female child, aged 8 years, admitted to hospital with general anasarca, unable to open her eyes; distension made palpation of the abdominal viscera impossible: there was intense albuminuria. The provisional diagnosis was ankylostomiasis, but examination of the blood showed the presence of *P. malariae*. In the faeces the only ova found were those of ascaris; careful search on three occasions of the faeces in bulk, after administration of thymol and beta-naphthol, failed to reveal the presence of ankylostomes. Reference was made to a series of nine cases of a similar nature by Macfie, in which series, however, no details were given of examination of faeces. Dr. Dimock considered the oedema to be more severe than any he had observed in uncomplicated helminthic infection.

The PRESIDENT drew attention to a report<sup>1</sup> of the Rockefeller Foundation in which it was recognized that severe malaria cachexia was fairly often mistaken for hookworm disease.

Dr. J. Y. WOOD demonstrated two cases of beri-beri and one case of anaesthetic leprosy.

The first case of beri-beri was in the stage of exaggerated knee reflexes, the second had absence of knee-jerks. The first had no alteration in the cardiac rhythm, a feature of the second case. Both cases presented deep hyperaesthesia, Romberg's sign, and oedema over the tibiae. The drug treatment adopted for these

the dose had been raised from 5 to 20 minims.

Dr. E. J. WRIGHT showed two cases.

The first was a male Syrian, aged 30, who gave no history of a primary lesion, had a rash which resembled a well-developed macular syphilide all over the body, the maculae being dusky in the lower part of the abdomen and legs. The rash was irritating and tended to become pustular. There was a history of sudden chill, pain in the joints, and two days later the rash appeared. The joints of his wrists were slightly swollen, and the temperature was 100° F. There was slight albuminuria; no parasites in the blood. The second case was that of a child who, in the course of three weeks, had lost a large portion of his right cheek and of his upper jaw from an ulceration of the cheek. No organism was found which could account for the condition; symptomatic treatment was given. The result of the healing process was the almost complete loss of movement of the lower jaw.

Dr. E. S. WALLS showed a specimen consisting of a tangled mass of ascarides, which had produced severe symptoms in a Creole child aged 7 years.

The symptoms at first pointed to an acute abdominal condition, the temperature being 101.5°, the pulse rate 130, and respirations 130. Deep palpation caused pain in the right iliac fossa, but there was no definite localized rigidity. Bimanual rectal examination revealed nothing positive; constipation was marked; in the urine nothing abnormal was found. For several days symptoms persisted, and the repeated administration of santonin was undertaken owing to a previous history of the vomiting of two round worms. The symptoms, temperature, rapid pulse and respirations, passed off two days before the ascarides were passed, as a result of administration of repeated doses of calomel. It was suggested by Dr. Walls that the localizing symptoms were due to ascaris, which caused obstruction, and the general symptoms were caused by their toxin, the elaboration of which ceased at their death probably two days before they were passed.

Dr. EASMON referred to a case of a somewhat similar nature which had been under his care in the Protectorate.

Dr. WALLS showed also a case of periosteal sarcoma of the tibia in a male Creole of 48.

There was a history of injury in April, 1922. In November an exploratory incision into a small swelling in the situation of the injury revealed organized blood clot. The wound healed, but a rapid increase of the swelling took place, and the skin broke down in the first week of January, 1923. By January 25th there was a large fungating growth. Two other cases shown by Dr. Walls were (1) a child with a sequestrum of blackened bone three inches

long projecting upwards from the middle of the tibia, and (2) a boy aged 7 years who had a foreign body (a piece of laterite, in the external auditory meatus necessitating post-aural incision of the cartilaginous meatus.

## Reports of Societies.

## DIET, DENTAL STRUCTURE, AND CARIES.

At a meeting of the Odontological Section of the Royal Society of Medicine on March 26th, Mr. W. R. ACKLAND presiding, Mrs. MELLANBY gave an account of some of her later work on the relation of diet, dental structure, and caries.

Mrs. Mellanby said that finally in this investigation had not yet been reached; until dental caries could be produced in living animals in such a way that each factor could be controlled and tested in turn, the exact etiology of this defect must remain obscure. The new evidence she had to bring forward related to the resistance of the teeth to caries after their eruption as evidenced by the production of secondary—or, as it was sometimes called, adventitious—dentine of different types. In her previous work, which she briefly reviewed, the main principles brought to light were the importance of a certain factor, which might be described as vitamin A, in the formation of the teeth and jaws and in resistance to infection, also the importance of other factors in the diet in relation to this first factor, and, again, the importance of the diet of the mother during pregnancy and lactation. Although vitamin A was important, yet it was only one link in a long chain, and the amount of this factor which was necessary in order to maintain normal conditions depended on the amount of other factors in the diet. If, for example, two puppies were fed on exactly the same deficiency diet save for the single difference that to one was given double the quantity of cereal that the other received, the one which received the additional cereal would grow more rapidly than the other, and the condition of the teeth would be worse.

Recently she had carried out an examination on 302 deciduous teeth of children, which had yielded the following results:

	No. examined.	Well formed; no Caries.	Normal Structure; Caries.	Hypoplastic	
				No Caries.	Caries.
Incisors ...	47	34	5	—	8
Canines ...	29	1	—	12	16
First molars ...	83	1	5	1	81
Second molars...	133	—	1	—	137
	322	35	11	13	242

Thus 84 per cent. of these teeth showed a hypoplastic condition on microscopic examination, and over 90 per cent. were in absolute agreement with the theory of a direct relationship between structure and caries.

In trying to find a reason for the exceptions, she was struck by the varying types of secondary dentine seen in the sections. In a number of the 11 cases of carious teeth which were well formed, the secondary dentine was badly formed, with interglobular spaces, and in another case where the structure was good the pulp was found to be filled with cementum so that it could not resist the onset of caries. An analysis showed:

	Good Secondary Dentine.	Bad Secondary Dentine.	No Secondary Dentine or no Reaction.
Structure normal:			
Caries ...	—	8	3
No caries ...	23	8	5
Structure abnormal:			
Caries ...	15	130	97
No caries ...	9	2	2

Apparently in the large number of carious teeth with abnormal structure which showed no secondary dentine the onset of caries had been so rapid that there was no chance of

<sup>1</sup> Report of Uninariasis Commission to the Orient, 1915-1916, p. 110.

secondary dentine formation. Secondary dentine which was formed when the diet was good contained no interglobular spaces; that formed when the diet was bad did contain such spaces. Secondary dentine was formed by attrition or in response to an attack of caries, and in the latter event it might be that the secondary dentine was formed so quickly as to allow no time for good formation, or else that the diet was not good enough to permit of such good formation. There was at least some evidence that those conditions which produced good enamel and primary dentine were just those conditions which brought their influence to bear upon the teeth after eruption. The diets which produced normal teeth in puppies were also those which enabled the animals to resist bacterial infection. If there was an outbreak of distemper or mange those animals which were receiving cod-liver oil, suet, whole milk, butter, or similar food, survived; and if they got the disease—as they did sometimes—they got it in a mild form. The deciduous teeth of children which resisted caries, although the enamel and primary dentine were defective, were found generally to have normal secondary dentine. These investigations were still in progress, and new points were emerging continually. Some critics of the work rather took up an attitude which could be justified if—but only if—claims to absolute truth had been made. What she had so far elicited was only part of the story; much more information was needed before dental caries could be fully understood.

Mr. J. H. MUMMERY said that structure was evidently not the only condition to be considered in regard to caries. There were teeth of very defective structure which were not subject to caries. There was some other associated factor in addition to structure. He thought it must be concluded that the enamel was not altogether out of the pale of vitality. There was something in the permeability of the enamel which was not yet fully comprehended.

Mr. F. W. BRODERICK said that Mrs. Mellanby had previously shown that diet did affect dental enamel, but he thought that diet could not be the sole agent. He believed that there was a connexion between endocrine derangement and susceptibility to caries or to pyorrhoëa. W. B. Cannon had shown that in certain emotions, including anger and fear, also in hunger and pain, the activity of the suprarenal was increased, and amongst other results there was an increase in the calcium salts in the blood. He thought it could be said that that calcium was definitely a part of the alkali reserve, and that in threatened acidosis the calcium salts would be taken to neutralize the blood, so that under those circumstances the salts would not be available for their ordinary purposes—for example, hypercalcification of the enamel after eruption. He regarded the association of the periods of liability to acidosis, endocrine derangement, and susceptibility to pyorrhoëa or caries as not entirely fortuitous. Endocrine derangement, whether brought about by vitamin starvation, by infections or toxæmias, by inherited instability, or by the emotions, would be likely to lead to dental caries or to pyorrhoëa, as the case might be.

Mr. A. T. PITTS said that two years ago he read a paper describing his findings with regard to deciduous teeth. Out of something like 4,000 children he found only some 15 cases of visible (that is, macroscopic) hypoplasia; now Mrs. Mellanby said that out of 300 teeth she found 84 per cent. to show this defect on microscopical examination. This gave rise to the question as to what was normal enamel, and what was the significance of the interglobular spaces, and as to which opinions might differ. As to secondary dentine, it was well known that its formation was normally the product of the human pulp, but whereas it was sometimes laid down as the result of a normal physiological stimulus, in other cases, as in caries, it was laid down as the result of a pathological stimulus. The character of the stimulus must affect the nature of the secondary dentine laid down. The dentine laid down as the result of attrition was better than the dentine laid down in response to caries. It seemed to him in the present state of knowledge with regard to the subject to be a little hazardous to argue that the character of the secondary dentine as laid down in caries could be correlated with the diet. It was only rarely that he himself found anything wrong with the diet, yet many mothers when bringing their children said that the teeth came through decayed. That was not so, of course, but it always seemed to him that imperfection of structure must be a very strong predisposing cause in these cases of premature caries. He did not think that carbohydrate stagnation was the controlling factor.

Mrs. MELLANBY, in reply, said that so little was known about the functions of the endocrine organs that it was difficult to base any theories as to the production of caries on something which itself had so little foundation. She also remarked that, as the result of attrition pure and simple, one might get good or bad secondary dentine with or without interglobular spaces.

## EPIDEMIOLOGY OF SURFACE DISEASES OF THE EYE.

At a meeting of the Section of Epidemiology of the Royal Society of Medicine, held on March 23rd, Mr. BISHOP HARRIS read, by invitation, a paper on the epidemiology of surface diseases of the eyes. Epidemics were now, he said, rare and of mild character; this was not always so. After the Napoleonic wars Europe was ravaged by what was known as Egyptian ophthalmia. A remarkably clear account of this as it affected English troops was given by Dr. John Vetch, surgeon to the 54th Foot. In a time when the influences of miasma, effluvia, and the like were held to be the causes of such affections, he recognized that direct contagion was responsible, and that both he and other officers were immune even when they examined cases with lenses with foci of one inch, provided there was no direct communication of matter. He also abolished barrack towels and substituted individual towels and daily washings with separate basins. The disease was a severe purulent conjunctivitis. He noted that gonorrhoea was rife amongst the affected men, and that the subjects of the disease were liable to a succession of urethritis, purulent ophthalmia, arthritis, and iritis. In these days they had to rely upon the massed figures of endemic cases to show the influences of various conditions upon these diseases. He dealt with five conditions—social, age, sex, seasonal, and the influence of other epidemics. Social conditions were dominant, because these made the distinction between clean and less dirty, and dirt was found to be directly associated with liability to conjunctivitis. By several methods of examination of hospital cases and school children this point was made abundantly clear.

With rare exceptions conjunctivitis was much more common in infancy than in school age, and cases got fewer during adult years. This was especially true of purulent conjunctivitis. Blepharitis did not appear until the third year, when measles was rife, and phlyctenulæ had a maximum at the fifth year, when the mouth was septic from the decay of the milk teeth. Angular conjunctivitis did not appear until the teens for the most part, and it was most common amongst the elders. Despite these exceptions there was clear evidence that infants were more susceptible to conjunctivitis than grown-ups, probably because they revelled in dirt. Females were more liable than males. The second quarter of the year, with the onset of the strong drying winds of March, was marked by the peak of incidence of conjunctivitis. Epidemics of the exanthemata were responsible for much conjunctivitis and for the initiation of many cases of chronic blepharitis, but in all cases there was evidence of lack of personal care as an aggravating feature. Phlyctenular conjunctivitis had been held by some to be a tuberculous affection. He found, however, that these eruptions had a seat of election, the lower and outer quadrant of the limbus, which had as a nerve supply the second division of the fifth, which also supplied the upper teeth. Further, the majority of cases were rapidly cured by simple ointments, one-half of all in one week, and only a fraction (one thirty-second) became chronic, extending for months and years. In these few there might be a paratuberculous relation. The mass he believed to be herpetiform eruptions set up by oral and nasal irritation in the poor and ill fed. It was remarkable that certain alien people whose food was richly impregnated with oil rarely suffered from the disease, yet they lived in the same quarter of London and suffered from dirt conjunctivitis in excessive proportion. Finally, he pointed out that exanthemata were responsible for a considerable share of blindness amongst school children, to the extent of one-fourth the total due to ophthalmia neonatorum. In these surface diseases of the eyes dirt and disease were remarkably associated, and education and the improvement of the standard of cleanliness must be looked to for the prevention of their ravages. The past showed immense advances in this direction.

The PRESIDENT said they recognized that ophthalmia was remarkable for its precision, but he did not know what

he had heard Mr. Bishop Harman's paper how well it could show the effects of social conditions.

Sir WILLIAM HAMER said he was greatly interested in the story of the suppression of barrack towels by Vetch, and wondered if there were any similar experience in the late war. The greater liability of girls to these diseases of the eyes was paralleled in many other conditions.

Dr. DUFFIELD remarked that there were increasing notifications of ophthalmia neonatorum, but blindness arising therefrom was less. He discussed the influence of flies and dust as the cause of seasonal variations of conjunctivitis. Dr. E. W. GOODALL doubted whether warmth was really a favouring influence for dirt as Mr. Harman had suggested in reference to the Egyptian figures. Dr. MAJOR GREENWOOD commented upon the slowness with which clear conclusions upon the nature of disease became common property. The exposition of John Vetch on purulent ophthalmia was so clear that it would seem certain of acceptance, yet it took years to become widely known.

The meeting concluded with a vote of thanks to Mr. Bishop Harman for his paper.

### HYPERTHYROIDISM.

A JOINT meeting of the Sections of Medicine and Surgery of the Royal Academy of Medicine in Ireland was held on March 16th, with Dr. H. T. BEWLEY (in the absence of the President, Dr. T. G. MOORHEAD) in the chair, when the SECRETARY read a paper, written by the President, to initiate a discussion on the subject of hyperthyroidism, its diagnosis, varieties, and treatment.

Dr. Moorhead reviewed the existing knowledge of the subject, and referred to the frequent association of persistent thymus with enlargement of the thyroid. Mental factors such as frights were undoubtedly often associated, and he gave details of two such cases in his own experience. The possibility of gastro-intestinal infection as an etiological factor was also mentioned. As regards diagnosis, he thought that the gastro-intestinal symptoms of hyperthyroidism were those most likely to be overlooked, but mistakes sometimes arose from neglect to examine the patient properly. In obscure cases a determination of basal metabolism would decide. Lymphocytosis occurred in simple goitre, and was valueless as a test. Tachycardia was, in his opinion, the most constant sign; loss of weight was also very important. The association of Graves's disease and myxoedema in the same patient was sometimes, though rarely, found. As regards prognosis, gain of weight and diminution of tachycardia under treatment were favourable signs, but in cured cases the goitre and the exophthalmos frequently persisted. He was strongly opposed to surgery in the treatment of the condition, and held that medical treatment, with x rays, would cure the great majority of cases with more certainty and safety than surgery. His own routine and technique were carefully detailed, and the results were claimed to be entirely satisfactory.

Sir WILLIAM WHEELER said that his interest had been stimulated by a visit to the late Dr. Kocher of Berne on three different occasions, and subsequently by watching the operative work of Mayo and Crile. He believed in the surgical treatment of cases of hyperthyroidism, as recent advances had made operations safe, and the mortality was almost negligible. He was of opinion that there were really only three types of goitre. The first was the colloid, seen in young girls, with full symmetrical neck, associated sometimes with extreme nervousness, and difficult to distinguish from hyperthyroidism. The basal metabolic rate was the only sure method of differentiation. Furthermore, this was the one type of goitre which responded to treatment with iodine, or its derivatives, or with thyroid extract. The second type was the adenomatous goitre; in these cases operation might be delayed, in consideration of the importance of the thyroid gland in adult life; but it should be remembered that adenomata frequently became toxic after a period of fourteen to sixteen years. Toxic goitre should be referred to as Plummer's disease; these cases differed in many respects from Graves's disease, and were more dangerous, as they gave rise to more certain degenerative changes in the viscera. In the third type were the hyperthyroid cases, which were regarded in a general way as Graves's disease. He was inclined to depreciate x-ray treatment on the grounds that if the dose was too big myxoedema followed, and if too small the patient had a relapse. If surgery became necessary after x-ray treatment, it was complicated

by the production of fibrous tissue and adhesions. The only fatal case which he had come across was a case of adenomatous goitre, which at the time of operation was thought to be non-toxic, but the patient died suddenly from myocardial degeneration. He pointed out that by a measurement of the basal metabolic rate the nature of this case would have been recognized; this test was not only of sure and certain diagnostic aid, but was a definite index to the result of treatment.

Sir JOHN MOORE said that he was physician to a girls' school at which there were about sixty pupils, and not a year passed but some of these girls were brought to him suffering from more or less enlargement of the thyroid gland. These patients did very well when treated for anaemia, and when moderate doses of thyroid extract were given systematically. In the early stages of ordinary goitre and of exophthalmic goitre he was of opinion that if the patient was made to rise, with a fixed neck, from the recumbent position it would almost certainly empty the thyroid gland.

Dr. A. A. MCCONNELL thought that the treatment outlined by the President was more surgical than medical, as the essential part of it seemed to be that he destroyed the glandular tissue by means of x rays. The question seemed to be, Was it safe to treat cases by gradual destruction of the glandular tissue by x rays, or was it better to treat them at once by operation?

Dr. W. C. MACFETRIDGE said that the causation of exophthalmos was one of the most interesting points in connexion with cases of hyperthyroidism. There were a number of views put forward to explain the protrusion of the eyes, and the one most commonly held was that it was due to excess of fat in the orbit. He thought there were several objections to this view. Exophthalmos came on very suddenly, and he had heard physicians say that they had seen patients in which it had come on acutely. He personally had known one case which had been caused by the patient weeping all night over the death of her father. The exophthalmos, he believed, disappeared after death, and if this were so it could not be due to excessive fat in the orbit. *Post-mortem* examinations in these cases were rare—in sixteen years there had only been three deaths in Guy's Hospital from exophthalmic goitre. It was curious if an abnormal amount of fat should develop in the orbit, while at the same time emaciation took place in the rest of the body.

Dr. G. E. NESBITT thought that x-ray treatment was capable of almost mathematical accuracy. It undoubtedly destroyed the glandular tissue, but neither it nor surgery made any attempt at getting at the underlying factor of the cause of this disease.

Dr. H. T. BEWLEY said that he had noticed the frequency of cases of colloid goitre, and he did not believe that they were cases of hyperthyroidism. He did not agree with the President regarding the persistence of the exophthalmos, as he had seen several cases which had been cured, and the exophthalmos had disappeared altogether. Regarding treatment, he thought that cases of the extreme kind should be treated, at first at any rate, by rest, sedatives, and x rays. Cases of medium severity he thought were best treated by surgery.

### ECONOMICS AND PUBLIC HEALTH.

At a meeting of the Society of Medical Officers of Health held on March 16th, with the President, Dr. T. EUSTACE HILL, in the chair, Dr. R. J. EWART read a paper entitled "The economic circumstances of the country as a whole, and the various rates by means of which health is measured."

He dealt in the first instance with the relationship of man to his bacterial environment, and suggested that the economic revolution of the nineteenth century was dependent on the control of small-pox. He supported his argument by numerous references to the reaction of certain populations to organismal changes, amongst which he included the disappearance of the economic surplus in the Northern States of Italy due to the introduction of syphilis in the year 1500, and as a consequence the close of the Renaissance. Passing from this theme the nature and peculiarities of the economic revolution of the nineteenth century were discussed, and the author seemed to be of the opinion that foreign trade was the best measure of its progress. This was shown to be capable of division into—first, a fluctuation measured by the percentage number of trade unionists employed from year to year, and secondly, a general steady upward trend as measured by the amount of food and other necessities of

life consumed per head of the population on what could be taken as an alternative of the value of real wages. After discussing in some detail the probable origin of fluctuation of prosperity the author compared by means of graphs the relationship between fluctuation in employment, value of real wages, and the death rate from certain causes. The conclusions arrived at may be briefly stated in the following manner. The change in the epidemiology of scarlet fever which occurred about the year 1850 would seem to have been due to the migration of whole families from town to town, according to industrial necessity. Previous to 1830 areas or towns seemed to react independently, afterwards the county reacted as a whole. The high degree of immunity at present attained was stated to be due to this cause. Dr. Ewart suggested that the changes in infantile mortality were due to variations in the bacterial content of the food supply. The rise previous to 1899, when a fall was expected, was said to depend on the deterioration of the milk supply, itself dependent on the increased time of transport, and the fall after that date was the replacement of this contaminated fluid by the milk product. The sex ratio at birth also seemed to be dependent on economic factors. It was stated that the influence of the food supply on the germ plasm naturalized the differential sex death rate before birth. Should, however, a sudden change occur in that community, these two factors become separated, and an excess of boys or girls arose according to the existing conditions. Referring to the general death rate, he laid stress on the fact that this was unaffected by fluctuation in prosperity, but was closely associated with the value of real wages. He explained this as being dependent on the Poor Law, which was so adapted as to maintain the health of the community during periods of depression, without interfering with its economic life. Lastly, Dr. Ewart expressed his opinion that the liberal food supply at the present moment was the main factor upon which the favourable state of the public health depended, but that the means adopted was interfering with the economic life of the community, and, as a consequence, the value of real wages might come down. He pointed out that if such did happen the general and phthisis death rates would rise, but that the infantile mortality would not be affected.

## Rebuelus.

### INJURY AND RECOVERY.

PROFESSOR W. J. V. OSTERHOUT, in his monograph *Injury, Recovery, and Death in Relation to Conductivity and Permeability*,<sup>1</sup> sets forth a number of highly interesting conclusions that he has arrived at after about fifteen years' study of the variations in conductivity that occur in plant tissues.

These conclusions are derived chiefly from measurements of the electrical conductivity of the seaweed *Laminaria*. The typical method employed was to cut out a hundred discs from *Laminaria* fronds, arrange them in a cylinder and measure the conductivity of the cylinder and the changes which occurred in the conductivity when the discs were immersed in salt solutions of varying composition. Electrical conductivity is a factor which can be measured with great accuracy, and by using a large number of discs of tissue the author has sought to exclude individual variations, and claims to have obtained results of an accuracy sufficient to justify mathematical analysis. "Throughout these investigations," he says, "the aim has been to apply to the study of living matter the methods which have proved useful in physics and chemistry."

The study of the elementary properties of living matter has undoubtedly reached a point from which the chief hope of advance lies in the application of the mathematical methods employed in physical chemistry; but it is equally true that it is only possible in exceptional cases to obtain with living matter results which are sufficiently accurate to make mathematical treatment profitable. The work of Professor Osterhout, however, seems to be of this exceptional character, and his conclusions relate to matters of fundamental importance.

An analysis of the curves of the rate of death and recovery of the author to the conclusion that

living protoplasm obeys the laws of chemical dynamics and that the differential permeability of cells, and hence their life, is dependent upon the concentration at the surface of the cell of an unknown substance "M." This substance, he thinks, is continually breaking down and is continually renewed by the cell. Hence the life of the cell depends upon a series of catenary reactions which may be represented as  $O \rightarrow S \rightarrow A \rightarrow M \rightarrow B$ . The cell is in equilibrium when the rate of change  $A \rightarrow M$  is the same as the rate of change  $M \rightarrow B$ . When the tissues are placed in a solution of pure sodium chloride the permeability increases until death occurs, and this change is attributed to an inhibition of the change  $O \rightarrow S \rightarrow A$ , and an increase of the rate of change of  $M \rightarrow B$ , in consequence of which the concentration of M steadily falls. Professor Osterhout shows that upon this assumption curves can be calculated which fit exactly the curves obtained in experiment. The greater portion of the book is devoted to the analysis, upon the lines indicated, of the curves obtained during the death of tissues and during their recovery from toxic influences, and the question of the mode of action of antagonistic ions is also analysed.

According to this conception life is a dynamic process depending upon the relative rates at which the different stages in a series of catenary reactions occur. This hypothesis promises to be fruitful, for by it the processes of death and recovery can be explained; it should be possible also to extend it to the study of the changes in irritability which cause rhythmic activity. A point of considerable importance is that a substance which acts as a member of such a chain of reactions may be of greatest importance to the organism, even though it is only present at any particular time in extremely small amounts.

The general conception that the death process occurs continually in the organism throughout life, and that death is only an acceleration of this process, has been frequently put forward before, but Professor Osterhout has for the first time advanced definite evidence in support of this conception.

Chapter V, which deals with the action of anaesthetics, is of special interest to medical science. The mode of action of anaesthetics is very clearly demonstrated; in low concentration they cause a decrease in the permeability of the cell, and this decreased permeability is reversible; in higher concentrations anaesthetics cause an increase in the permeability of the cell and this action is irreversible. Since complete reversibility is the most essential characteristic of the therapeutic action of anaesthetics, we are asked to conclude that the action of anaesthetics in therapeutic concentration is to decrease the permeability of living cells.

Owing to the diphasic nature of their action on permeability, the fundamental nature of the action of anaesthetics upon protoplasm has been a matter of dispute, and it is an advance to have the action of these drugs thus analysed quantitatively. Nearly the whole of Professor Osterhout's work has been done upon vegetable tissues, and considerable research will be necessary before it will be possible to say how far his conclusions are applicable to the more complex and more labile animal tissues; he has, however, provided a fundamental hypothesis for the behaviour of living protoplasm based upon mathematical laws, and this should provide a foundation for a large amount of interesting work. The monograph is concerned chiefly with Professor Osterhout's own work, which is more exact and complete than any other on similar lines; mention is made, however, of most other important work on these lines, and the book concludes with a selected bibliography of about 300 references.

### HEART DISEASE.

THE appearance of a fifth edition of Dr. BROCKBANK'S book on the *Diagnosis and Treatment of Heart Disease* so soon after the fourth speaks well for its popularity. On this occasion the author has taken the opportunity of altering the arrangement of some of the chapters and of making considerable additions to the text that have increased the number of pages by about one-half. It still remains, however, a small book and will be useful not only to students in their clinical work but also to general practitioners who are seeking a short statement. The first ten chapters deal with the ordinary

<sup>1</sup> *The Diagnosis and Treatment of Heart Disease: Practical Principles for Students and Practitioners.* By E. M. Brockbank, M.D. 1922. (See 210, p. 110, 1922, p. 110.)

methods of physical examination, special attention being paid to auscultatory phenomena and the interpretation of the various murmurs that may be present. Some of the views expressed may not meet with universal acceptance, but the writer has the courage of his convictions and gives a reasoned opinion on all debatable points.

The chapter on cardiac irregularity is brief but practical. Two plates of electro-cardiograms have been used for the purpose of illustrating various defects of cardiac rhythm, but the aim of the writer is to explain the varieties rather than to discuss the analysis of graphic records. Probably one of the most useful chapters is that dealing with practical points in the treatment of cardiac disease, and we note here, as elsewhere in the book, that attention is directed to many matters which are often not sufficiently impressed on the student in other and larger textbooks, but which are of much value in actual practice. Other sections treat of septic endocarditis, auricular flutter and fibrillation, paroxysmal tachycardia, pericarditis, angina pectoris, the heart in school children, etc., while the closing chapter is devoted to examination for life insurance.

The additions which have been made to this book will increase its usefulness, and have made it very different from *Heart Sounds and Murmurs*, the title under which the first edition appeared in 1912. Any minor criticisms that we might have been tempted to make are more than outweighed by its many excellent qualities, and we are convinced that it will be much appreciated by an increasing circle of medical men who will find in it many practical hints. The students in the Manchester school should be particularly grateful to the author.

#### RADIOLOGY.

STILL another book is added to the increasing number published of late on the subject of the more recent methods of x-ray therapy. This one, under the title of *La Radiothérapie Profonde*,<sup>1</sup> is from the pen of Iser Solomon, radiologist to the Hôpital Saint-Antoine, Paris, who acknowledges in his preface his obligations to the two well known French authorities Drs. A. Bécère and Belot. By far the larger part of the book is taken up with instrumentation and physics, and very great stress is laid upon the point that the great advances in technique in recent years have only been made possible by the more precise methods for the measurement of x-ray dosage, and notably by the perfection of the iontoquantimeter. It cannot be said that there is anything new in this first portion, but the author deals with his subject in a simple and straightforward manner. The author first states the fundamental principles underlying the methods of deep therapy, and then enters into minute detail on the subject of the absorption of x-rays; this chapter is illustrated by many tables. In the second chapter the apparatus designed for the production of these high-voltage currents is described, and tubes—the boiling water, the Lilienfeld, and the Coolidge tubes—and accessory apparatus are dealt with in succession. The third chapter discusses all the important methods and instruments for the more accurate measurement of dosage; the larger part of the space is taken up with the ionization methods and the various devices suggested by Lilienfeld, Szilard, Friedrich, and the author. All these methods are illustrated. Having given about one hundred and twenty pages to this part of the subject, the author dismisses the important question of the result of treatment in only thirty more. He deals first with what is termed “benign affections”—including fibromata of the uterus and allied conditions, tubercle, blood diseases, and maladies associated with the endocrine glands. The author agrees with Bécère that for uterine fibroids x-ray therapy is the treatment of selection, and that it gives better results than surgery, without any risks. The second and final part discusses the results of treatment of neoplasms; the author points out that, whilst it is impossible to accept the theory of one exact lethal dosage for the different types of malignant disease, undoubtedly the results of x-ray treatment have been much improved by the administration of larger and more uniform dosage; that in the treatment of cancer of the uterus the results are equal to those obtained by either radium or operation; and that intensive x-ray therapy must rank as one of the most powerful therapeutic agents in this disease.

WITHERBEE and REMER, under the title of *X-ray Dosage in Treatment and Radiography*,<sup>2</sup> give an account of the methods they have themselves used and developed during the past few years. The authors have had no experience of the latest treatment for cancer, using high voltages of above a ten-inch spark-gap, and their book deals with tubes working between a three- and ten-inch gap and at distances from the skin varying between six and twenty inches. In the first chapter, in which the unfiltered x-ray dosage is discussed, the principles of their method, based upon the four fundamental factors of the voltage, the milliamperage, the time, and the distance, are explained. X-ray burns in radiography are next considered, and it is shown that this method of estimating x-ray dosage is also applicable to the determination of the number of plates which can be taken without danger to the patient. There is also a chapter on filtered x-ray dosage, followed by short notes on the principles and the cause of x-ray burns. The remaining portion is allotted to the technique of treating affections of the throat and tonsils, and tuberculous glands, skin diseases, uterine fibroids, leukaemia, and Hodgkin's disease. As a whole the book is a simple account of the technique used by the authors, a technique which they consider easy to follow and safe for the patient. The book will be of especial value to those using an x-ray apparatus who have not yet acquired the special knowledge necessary for its safe use.

In the introduction to his book on the x-ray diagnosis of gastro-intestinal diseases<sup>3</sup> SCHLESINGER points out the importance of the conventional Continental view that the x-ray examination of the digestive tract should be regarded as an aid to the clinical examination. He indicates clearly that the x-ray examination, even under the most favourable conditions, can only present a fairly faithful outline of the interior of the organs examined—that is, if an opaque material is introduced into any part of the alimentary tract the picture obtained on the screen or plate will be a reproduction of the lumen of the structure, showing any irregularity of its lining walls, together with the movements and the position of the organ. It is clear that, if the examination be thorough, any departure from the normal may be revealed. The picture obtained may show a defect, and from the appearances of the defect it is possible to indicate a lesion, but the exact nature of the lesion can only be determined by exhaustive investigations in which the clinical examinations play an important part. For example, a defect in the stomach contour may indicate the presence of a chronic ulcer, a cancer of the stomach, an artefact, the presence of adhesions, an irregular contraction, or an extra-gastric lesion causing pressure effects. Schlesinger, therefore, throughout his book adheres to the principle of correlated diagnosis, and in our opinion this is the correct method. He, on the other hand, believes in the use of the direct method so general in America, and insists upon the point that the radioscopy and the radiographic are indispensable. The serial method is advocated in the routine examination, in which he employs a number of plates exposed at intervals. The book is illustrated chiefly by a large number of excellent diagrams; these are of great teaching value, and draw more clearly the attention to the diagnostic points than a number of radiograms. The latter, unless very well produced, fail to show the finer points in diagnosis. The diagrammatic method has a distinct value, more especially when the drawings are made by a worker whose experience is so great as that of Schlesinger. The book is a worthy record of the work of one of the pioneers in x-ray gastro-intestinal diagnosis, and as such should find a place in the library of all practising radiologists and teachers.

#### MATERIA MEDICA FOR DENTISTS.

MANY remember the days when “Materia Medica and Therapeutics” had their place as one of the early studies in the curriculum of the “Conjoint Board.” When we had passed that first examination what knowledge was ours! what power against disease! There was a Latin name for everything, an antidote for every symptom. We had found an exact science! Disillusion followed when hospital practice revealed the far too frequent impotence of our drugs and the inapplicability of our knowledge. These were the thoughts and memories

<sup>1</sup> *X-ray Dosage in Treatment and Radiography*. By William D. Witherbee, M.D., and John Remer, M.D. New York: The Macmillan Co. 1922. (Capp. 8vo, pp. vi + 85; 4 figures. 8s. net.)

<sup>2</sup> *Die Röntgenphysik der Magen und Darmkrankheiten*. By F. Schlesinger. Zweite, neubearb. Urban und Schwarzenberg, 1922.

<sup>3</sup> *La Radiothérapie Profonde*. By Iser Solomon. Paris: Masson et Cie. 1923. (Imp. 16mo, pp. 152; 40 figures. Fr. 9 net.)

awakened by a perusal of FRANK COLEMAN's *Materia Medica for Dentists*.<sup>6</sup> Deodorants, antiseptics, astringents, counter-irritants, drugs innumerable! Has dentistry benefited by them? How many are used by the average dentist?

This is not written in disparagement of Mr. Coleman's work; on the contrary, we strongly recommend the book to every dentist; it is only that drugs have been disappointing, and the question arises as to how far the experienced dentist has travelled on the same road.

In this, the fifth, edition the pharmacological classification of drugs has been again followed, more information has been given on vaccine therapy and organotherapy, and short accounts of electro- and radio-therapy, vitamins, and delayed chloroform poisoning and other subjects have been added. An abstract of the new Act on the sale of poisonous drugs has been provided. On the other hand, the chapters on ionic medication and the bleaching of teeth have been curtailed. There are short but well written and instructive chapters on such specially dental subjects as mummifying agents and cleansing of the mouth and teeth; the latter includes a very good discussion on tooth powders, pastes, and washes which should not be without interest to the general practitioner.

Only occasionally is the author not quite clear, as in the repeated use of the word "solution" in explanation of colloidal solution, or in the presentation of the disadvantages of caustics. Occasionally, too, his opinion may be challenged, as for instance, that alcohol is a cerebral stimulant, or that purging should precede a general anaesthetic. Perhaps also the statement (quoted from Bruse) that "a natural mouth will be found to be quite free from food debris half an hour after a meal" may not meet with universal acceptance.

A fifth edition indicates an established position, and in our opinion the book well deserves its popularity. It is dedicated to Douglas Gabell and Harold Austin, the authors of the former editions.

#### PRACTICAL DERMATOLOGY.

PROFESSOR GOUGEROT's work, *La Dermatologie en Clinique*, favourably reviewed in these columns on its first appearance in 1917, has now reached its third edition.<sup>7</sup> This is the best evidence of a success thoroughly well deserved. The book is divided into two parts, the first devoted to general considerations of diagnosis and treatment, terminating with a most useful table of the principal external remedies, describing their action and giving the percentage strength in which they are used in their various preparations, solubilities, indications, and incompatibilities. The second part treats of the various affections of the skin. The new edition has been thoroughly brought up to date, and the last chapter, on "Dermatoses exagérées et simulées" (dermatitis artefacta), is most interesting. Much of it is founded on the author's experiences during the war, the influence of which is also seen in a previous chapter on the cutaneous complications of wounds. Another important subject, not usually dealt with adequately in textbooks of dermatology, is treated in the chapter on "Dermopidémies microbiennes," the name given to those lesions due to streptococcal infection which simulate eczematous eruptions. First recognized by Sabouraud some twelve years ago, they frequently arose in the neighbourhood of infected wounds during the war. Their proper treatment was a matter of considerable importance. Nevertheless, they have seldom been systematically described in works on the skin. Here they are given the prominence they deserve. Professor Gougerot possesses all the charm of style and incisiveness of expression we are accustomed to expect from our Gallie allies; his book is a delightful to read and well arranged. The illustrations, which are very numerous, maintain the high standard set in the former editions. With few exceptions they give a very good idea of the condition depicted. Everyone interested in the diseases of the skin should read Professor Gougerot's book, for in it will be found much that is stimulating and suggestive. The general practitioner will like to know that it is one of a series of manuals entitled "Comment guérir." Can he resist an invitation so seductive?

<sup>6</sup> *Notes on Materia Medica, Pharmacy, and Therapeutics for Dental Students and Practitioners*. By F. H. Coleman, M.C., L.R.C.P., M.R.C.S., L.D.S. Fifth edition. Oxford Medical Publications. London: H. K. Lewis, and Hodder and Stoughton. 1922. (Cr. 8vo, pp. iv+308. 10s. 6d.)

<sup>7</sup> *La Dermatologie en Clinique*. By J. H. Gougerot. Third edition. Paris: A. Maloine et Fils. 1922. (Cr. 8vo, pp. xi+852. 210 figures. 75 fr. 35.)

#### NOTES ON BOOKS.

THIS small book on *Infantile Cirrhosis of the Liver*,<sup>8</sup> by Dr. S. K. MUKHERJI, gives an account of a disease that has received very little notice in medical literature. According to the author, it is a serious and not uncommon disease in infants in India, and is a clinical entity separate from other causes of jaundice in infants and young children. Castellani, on the other hand, doubts its claim to separate recognition, and suggests that it may be a form of kala-azar. The author gives a short account of forty-eight cases, forty-five of which occurred in the first two years of life. The features of the disease are slowly progressive jaundice, fever and constipation, with great enlargement of the liver, and moderate enlargement of the spleen; death usually occurs within three months of the onset. The liver, according to Gibbons, shows at first a fine intralobular cirrhosis, followed later by coarser interlobular fibrosis in which numerous bile ducts are prominent. The disease is apt to occur in successive children of the family, and specially affects Hindus: it is rare among Anglo-Indians. The author makes out a good case for further investigation.

Mr. SAMLER BROWN's guide book, *Madeira, Canary Islands and Azores*,<sup>9</sup> now in its twelfth edition, contains the information tourists or invalids require about climatic conditions, steamship routes, fares, hotels, paths, and where the water is drinkable and where it is not; there are many excellent maps and illustrations. The historical notes are interesting, and there is a delightful chapter on the lost continent of Atlantis. The author states that the meteorological statistics compiled in the *Cañadas* and *Izafia*, Tenerife, at an altitude of over 7,000 feet, are the first tabulated statistics to be published. The Spanish Government is building a sanatorium in the *Cañadas*, on a site 7,285 feet above the level of the sea, at a cost of £90,000.

To give a description of modern conceptions of constitution of the chemical atom is not a simple task: to do so in popular language is still more difficult, but the attempt is made by Mr. J. MILLS in a little volume entitled *Within the Atom*,<sup>10</sup> which the jacket informs us is a popular view of electrons and quanta. The non-scientific reader, we expect, will find it laborious reading. The author begins by trying to discard scientific terms, but as he progresses falls more and more into their use, so that he has found it necessary to add a glossary. The ramifications of the subject into many branches of physics and chemistry can only be followed by those who already have some acquaintance with these sciences. But if the matter should prove too deep for the non-scientific reader it will be perused with interest and advantage by many who, having a certain knowledge of physics and chemistry, still desire a better understanding of the mechanics of the atom.

We have received the first number of *Clinica y Laboratorio*, a new Spanish journal of medicine and surgery to be published monthly at Saragosa under the editorship of Dr. Ricardo Horno Alcorfa. The first half of this issue contains original articles, and the second half abstracts from current medical and surgical literature. The original articles consist of papers on the treatment of jejunal ulcer following gastro-enterostomy by Dr. Urrutia, on auto-serotherapy in pulmonary tuberculosis by Dr. Codina, on diverticula of the oesophagus by Dr. V. Fairén, notes on hydrocephalus by Dr. Galán, treatment of injuries of the soft parts of the cranium by Dr. Vidaurreta, diagnosis of acute appendicitis by Dr. Rivas, and a description of Heister's eighteenth century treatise on surgery.

The title *Half-Past Bedtime*,<sup>11</sup> which suggests something between sleep and waking, aptly conveys the spirit of Dr. H. H. BASHFORD's book of short stories for children. The delicate fantasy of the tales and the charm of the author's drawings (for he is his own illustrator) will be appreciated by young people of all ages. Each of the fourteen stories has its own picture, and the intervals between prose and picture are filled in with jolly little verses from the same gifted pen. It must be a great asset to a household to have a father who can do the whole thing "just so."

<sup>8</sup> *Infantile Cirrhosis of the Liver*. By S. K. Mukherji, M.D. Indian Medical Record Book Department. 1922. (Cr. 8vo, pp. 9 illustrations. Rs. 2/8.)

## THE SCHICK TEST AND SOME EPIDEMIOLOGICAL REFLECTIONS.

THE Report on the Schick Test, Diphtheria and Scarlet Fever, issued by the Medical Research Council,\* was briefly mentioned last week. Its subtitle, "A Study in Epidemiology," is justified by its general tenor and by certain hypotheses put forward by the author, Surgeon Commander S. F. Dudley, R.N.

His practical observations were made in the Royal Naval School at Greenwich: the number of residential boys averages about 1,000, all of good physique, under constant medical supervision, and living under satisfactory sanitary conditions; in addition there are about 100 day boys who mix freely with the boarders at work and play and at some of the meals. The circumstances were favourable for the study of the origin and spread of infectious disease, and this report describes an exhaustive research in the two diseases diphtheria and scarlet fever as they occurred in this population.

The immunity condition of the school as regards diphtheria was first examined by means of the Schick intracutaneous test, which was found to be a very reliable method for ascertaining who are immune to diphtheria. The boys were grouped into three classes according to their reactions:

1. *Positive reactors* (susceptible to diphtheria).
2. *Negative reactors* (immune to diphtheria).
3. *Pseudo-reactors* (either susceptible or non-immune).

A certain amount of experience is necessary in interpreting pseudo-reactions; the report states that there will always be a few frankly doubtful reactions due to confusion caused by pseudo-reactions, but with repeated readings the error should not exceed 2 or 3 per cent. The transitory pseudo-reactions, although very variable in intensity, can be easily distinguished from the specific Schick-positive reactions, and are due to an anaphylactic or allergic condition of the skin caused by previous contact with diphtheria bacilli. The positive and pseudo-reaction combined is often an intermediate stage in the development of immunity; it may be of only a few months' duration, and therefore indicates recent contact with diphtheria bacilli. It does not hold that all individuals who give a Schick-positive reaction are equally susceptible to diphtheria; they may possess a certain amount of resistance and be immune to ordinary doses of diphtheria bacilli, only contracting the disease when heavily infected. A negative reaction is to be attributed to diphtheria antitoxin in the blood, and may be due to previous disease or to previous recognized or unrecognized contact with virulent diphtheria bacilli. Second attacks of diphtheria are not common, and it is concluded that "one attack of diphtheria confers immunity in the vast majority of instances, even if the Schick reaction remains positive."

### Diphtheria Carriers.

Some valuable information was obtained concerning diphtheria carriers. The swabbing of the throats of the whole population revealed the fact that diphtheria may spread in an institution when the carrier rate for virulent diphtheria bacilli is as low as 1 per cent. Whereas carriers of avirulent diphtheria bacilli may be either positive or negative reactors to the Schick test, carriers of virulent diphtheria bacilli always give a negative Schick reaction. In view of the fact that any inflammatory condition of the throat renders the subject more likely to be a carrier, the diagnosis of diphtheria can only be regarded as certain when virulent diphtheria bacilli are isolated, the Schick reaction is positive, and a characteristic pseudo-membrane is present. Should any of these characters be absent or unknown, "the diagnosis is no longer a certainty, but becomes a matter for debate, to be settled according to the prejudices of the clinician or laboratory worker." It is obvious that the clinical characters are the most important factors in diagnosis: for practical purposes bacilli indistinguishable morphologically from diphtheria bacilli may be considered virulent if the culture comes from a clinical case. But in unselected healthy subjects bacilli morphologically identical with diphtheria bacilli may be avirulent in 60 per cent. of cases.

No relation was found to exist between diphtheroids of the Hoffmann type and true diphtheria bacilli. A study of the distribution of cases of diphtheria in the dormitories of this institution showed that the spread of bacterial infection takes place more frequently in the sleeping quarters if the distance between the beds is small.

### Mode of Spread: Penholders as Fomites.

Scarlet fever and diphtheria spreading in the same environment show striking similarities, but there is no reason to suppose that there is anything in common between their biological causative agents. Early in an epidemic, before the number of immune individuals is numerous, scarlet fever spreads directly from case to case, but it is probable that diphtheria spreads by chains of contact carriers from case to case. In both diseases the chief mode of spread is undoubtedly from one individual to another, but convincing evidence is adduced that fomites, such as penholders which boys have sucked and which are used as common property, can under certain conditions act as an indirect cause of the spread of scarlet fever and diphtheria. Virulent diphtheria bacilli were isolated from penholders which had been sucked by boys harbouring these organisms in their mouths. The results of repeated Schick tests on the population of this school, kept as it was under constant medical supervision, have shown that during an epidemic many individuals may become immune to diphtheria without showing any symptoms. The same applies to scarlet fever and probably to other diseases as well.

### "Velocity of Infection."

To explain the fact that far more infection took place in the dormitories than outside them the author has propounded a principle termed "velocity of infection." He argues that in many infectious diseases there is a certain minimal dose of infective agent necessary to cause the disease, and that a smaller dose is destroyed by the defensive mechanisms of the body.

"If a subject receives a number of subminimal doses which, when totalled, exceed a minimum infective dose, it is reasonable to suppose that it must depend on the rapidity with which these fractional doses are received as to whether or not he falls a victim to the disease in question—that is to say, as to whether the rate at which the doses of infective agent can be dealt with is greater than the rate at which they are received."

The velocity of infection is therefore the resultant of (1) the velocity at which a subject receives doses of a pathogenic agent, and (2) the velocity with which the immunity mechanisms of the subject can destroy this infecting agent.

This principle of the velocity of infection is held to explain the puzzling fact that there were no cases of diphtheria or scarlet fever amongst 103 day boys who played, worked, and ate with the boarders for over a year, yet 300 of the boarders with whom they mixed developed one or other of these diseases. During the day the immunity mechanisms were able to neutralize as rapidly as received the occasional doses of infective agent, to which it is assumed all were exposed; the conditions existing in the dormitories at night allowed of the continuous bombardment with infected droplets of saliva, so that the velocity at which the infective agent was received was greater than the velocity with which it could be destroyed by the mechanisms of resistance. This principle, it is thought, may account also for the development of immunity without symptoms and explain other difficulties in practical epidemiology.

During an epidemic of diphtheria many boys increased their resistance to diphtheria without manifesting any symptoms and without even developing recognizable antitoxin in their blood. There took place, therefore, a coincident "epidemic of immunization" among those who never even permitted a multiplication of the subinfective doses of the biological agents of the epidemic to which they had been exposed. At the same time there occurred an epidemic of contact carriers in the school. The author concludes that the information which may be derived from the consideration of this "epidemic immunity" should "soon do away with the necessity for postulating unknown mysterious influences as factors in an epidemic constitution."

DR. GEORGE WILLIAM PATERSON, colonial surgeon, has been reappointed to be an official member of the Legislative Council of the Island of Grenada.

SOME 350 members of the American College of Surgeons, with their families, have sailed on a cruise to South America, which will occupy about two months. The purpose of the trip is the promotion of professional and social relations between the surgeons of the United States and those of Central and South America. Meetings and clinics will be held at the various cities, and the medical schools and hospitals will be visited. At Colon, Panama, the party will be present at the laying of the foundation stone of the Gorgas Institute of Tropical Medicine.

SATURDAY, APRIL 7TH, 1923.

## THE SCHOOL OF HYGIENE.

THREE weeks ago we took occasion to refer to the fact that decisions must shortly be taken which will necessarily affect the whole future of the School of Hygiene, an institution that ought to have a very great influence in determining the manner in which practical hygiene and the sciences upon which it rests shall be studied and taught in this country. The problems before the founders and governors of the new School of Hygiene are not easy of solution. When it is a question of starting a new venture there is commonly a temptation to discuss it in terms of persons rather than in terms of ideas; and it is true that the decisions of an appointing body must be guided largely by personal considerations, for it would be idle to prescribe the doing of such and such things unless persons able to execute the tasks could be produced. Fortunately we can ignore personal factors and need attempt only to indicate the general scope of the work and the ideas which, having regard to that scope, must dictate the choice of personnel. The subject, thus limited, may be considered from three aspects—the type of pupil, the ideal curriculum, and the professorial organization of that curriculum.

All the students of the school will be post-graduates, but the preliminary knowledge they will possess will vary much. If we provisionally classify the main groups of subjects expected to be taught we shall have (1) bacteriology, (2) chemistry and physics, (3) applied physiology and hygiene, (4) parasitology, (5) medical statistics and general epidemiology, (6) public health administration, and (7) tropical medicine. The majority of students who have just graduated in medicine may be assumed to possess a sound knowledge of the elements of (1) and (2), some acquaintance with the leading principles of (3), but no knowledge whatever of the remainder. A minority of entrants, small numerically but of great importance, will possess more than an elementary knowledge of some one of these branches, and will seek in that subject graduate instruction of an advanced type. Again, there will be some who, while starting on the same level as the majority, will wish to extend their knowledge of a particular branch beyond the average need. This inevitable heterogeneity of the student class will make the planning of the curriculum more difficult—and, of course, more interesting—than if the question were merely one of bringing a batch of elementary students up to a common standard. Nevertheless, in shaping the curriculum it will probably be necessary to give to the needs of the elementary students the first consideration, and the requirements of the General Medical Council for a Diploma in Public Health will naturally be a point of departure.

There is, however, no reason why the precise allocation of times—which are minimum requirements—in the Council's rules should be adhered to. There is, for instance—even if the existing examination schedules are maintained—good reason for rearranging the instruction in meteorology and climatology and in vital statistics and epidemiology. Physical and chemical meteorology should be associated in time with the course of chemistry and physics. The study of climatology is more appropriately deferred until the student has a grasp of medical

statistics and epidemiology. The elements of vital and medical statistics should be taught contemporaneously with chemistry and physics. These elements are the tools the public health officer must employ in his daily work, and, although epidemiology is very far indeed from being a mere synonym for medical statistics, it is true that the main data of epidemiology are statistical in form and can only be utilized by a person familiar with the elements of statistical method.

The obvious danger to avoid is a watertight division between the two aspects of the course—the scientific, represented by Part I, and the technical, represented by Part II. Thus, in Part II we have the Principles of Public Health and Sanitation. In this course the student must learn the actual working of a very complex machine or set of machines; this instruction will be purely technical, but unless what may be called the embryology of these machines is understood, the reason why such or such principles of action have become established will not be appreciated. The embryology of the machines is written in the classical researches of the sanitarians of the nineteenth century; these pioneers employed various methods of investigation—clinical, bacteriological, statistical; the detailed study of their work must be co-ordinated with that of the methods of investigation, largely the theme of Part I. The rules make no provision for the study of applied physiology, owing, it must be supposed, to the lack of facilities for instruction in existing institutions. But it would plainly be wrong to discourage the development of a new and spaciouly planned institution. It follows that the elementary curriculum of the school should cover the whole of the instruction needed to meet the minimum requirement and more besides. The additions should be very great under the heading of applied physiology, quite appreciable in the matter of medical statistics and epidemiology.

The next point to be made is that the bulk of the teaching must be practical—there must be as few formal lectures as possible. The General Medical Council has already imposed this stipulation in the teaching of bacteriology and chemistry. It is equally important in other subjects. To attend lectures on, say, the methods of statistics is, for the ordinary student, a solemn farce unless he performs under supervision all the statistical operations described. This requirement carries with it that of small classes; it is as easy to preach to sixty students as to six; no man can efficiently conduct a class on, say, the methods by which knowledge of the means of transmission of diphtheria was acquired, with many more than six students, because such a class ought to be arranged on what has been called the *Seminar* system. The professor issues beforehand a list of the original authorities, each member of the class is expected to study an arranged portion of the literature and to come to the class prepared to give a critical account of what he has studied. This account is discussed and the students are made to feel that they are collaborators in an investigation, not mere sponges or transcribers of notes. Of course the method presupposes a certain intellectual maturity in the students, an assumption which can safely be made in post-graduate institutions.

The fascination of good public health research has not even yet been properly appreciated; textbooks of hygiene and preventive medicine are dull. But they ought not to be dull. We all love detective stories; there is a steady sale for reprints of criminal trials. It is fascinating to unravel the skeins in which human lives are involved. But there is as much human interest in the story of the great epidemic of typhoid at Maidstone, in following up, criticizing, and amplifying in the light of more recent information the evidence submitted at the public inquiry, as in trying to decide exactly how Palace

poisoned Cook at Shrewsbury seventy years ago. The public health annals of this country are full of such instances—not many perhaps on so large a scale, but many of equal interest. One of the causes of dullness in these matters is the attempt to cover too large a field, an attempt the didactic lecturer or the writer of an examination textbook feels bound to make. A careful study of a series of local epidemics of any one disease, the professor acting as the chairman of a group of researchers, would be both more interesting and far more educative than a session of formal lectures on the whole field. The system of instruction in a post-graduate school of hygiene should be penetrated with this idea. If the soundness of this principle be accepted, then it must influence the professorial organization. Administrative convenience will require that the number of full professors should be small, but each professor should regard himself rather as the chairman of a group, *primus inter pares*, than as an old-time lecturer with demonstrators.

Such are the general principles which, we venture to submit, the system of the new school should embody. We hope that it will give a sound general education to all its students, and facilities for special, more advanced and technical, instruction to some, but that in all departments instruction and research will mutually assist one the other. We do not wish to see either a mere machine for enabling youths to pass certain examinations or a temple of esoteric study and academic research.

### PHOTOSYNTHESIS AND SEA AIR.

Just eighty years ago Morren found that in the surface sea water near St. Malo the amount of oxygen was greatest and the amount of carbon dioxide smallest in bright weather, but the statement seems to have attracted no attention until recently, when the experiments of the late Professor Benjamin Moore on photosynthesis and the results of the prolonged studies of Sir William Herdman, in which Moore shared, on the plankton<sup>1</sup> of the Irish Sea, combined to awaken wide interest in the fact that seasonal variations of vegetation in the sea are determined by the seasonal variations of the amount of sunlight. From an examination of the records of fifteen years (1907–21) Herdman states<sup>2</sup> that there can be no question about the fact. There is always a great increase of the phytoplankton during the early spring: the first to multiply are the diatoms, which begin very rapidly to increase during the first fortnight of March, and reach a maximum in April or May, or at latest in June; at the time of their maximum hundreds of millions may be taken in one haul. About a month later come the dinoflagellates, and then the copepods (entomostracous crustaceans), which reach their maximum numbers at some time between June and October. The copepods devour the diatoms; young fish, and some adult fish, devour the copepods; the increase and distribution of fish thus depend in some measure, possibly a very large measure, on the number and distribution of the copepods and therefore indirectly on the number and distribution of diatoms. This relation is emphasized by the fact that many larval fishes feed on the diatoms directly; Herdman has found the stomach of the infant plaice full of them. In nine out of thirteen years the diatoms became abundant just before the very young plaice were set free, which happened in the first half of March, but in four years the diatoms were late and the young fishes

hatched in due time may not have found enough to eat. Fish hatched too early (February) seem always to run some chance of being starved.

All the investigations made on photosynthesis are in accord in establishing that the process is properly so termed and that it is due to light, not warmth, although, other things being equal, its velocity increases as the temperature rises. The general principle is illustrated by the phytoplankton of the Irish Sea, for in March, when its great spring increase begins, the temperature of the water is still low.

In a recent paper<sup>3</sup> Dr. William Butler and Mr. J. H. Coste have reported some observations on the seasonal variations in the dissolved oxygen content of the water of the Thames estuary, made in the course of a public health investigation for the London County Council. The starting point was the discovery, during the summer of 1914, that the water of the Thames estuary contained a proportion of oxygen greater than was required for saturation with atmospheric oxygen of water of the observed degree of salinity. This is spoken of as supersaturation. May and June were the months in which it was greatest, but the degree varied very much; in 1918 the maximum (June) was 177.5 per cent., in 1922 (May) only 116.3. The lowest degrees of supersaturation were observed in January, February, and March, and are within the limit of experimental error. The spring rise seems to be sudden, as the maximum may be reached in May, but unfortunately very few estimations were made in April. The plankton of the Thames below Southend, where the estuary may be said to begin, has not been fully studied, but Mr. E. T. Butler began a regular microscopical examination of the sediment from the water in July, 1921, and by September, 1922, had accumulated observations which are in general agreement with those of Herdman on the other side of England; he made rough estimates monthly of the numbers of diatoms, light green growths, and dark green (or blue) growths. He found that the diatoms and the light green growths began to increase rapidly in May, reached maxima early in July, and then rapidly decreased. What appears to happen is that the green growths and diatoms, stimulated by the sunlight, break up the carbonic dioxide, fixing the carbon and liberating the oxygen, which escapes only very slowly if the water be still. This is the condition to which the term "supersaturation" is applied, not perhaps quite happily, because it refers to the amount taken up from the atmosphere of the air, whereas from an atmosphere of pure oxygen nearly five times as much would be dissolved. The fact, however, serves to explain why the oxygen liberated by the growing vegetation does not at once escape. As the carbon dioxide is used up by the growth of the minute sea vegetation the water tends to become less and less acid, and in one set of observations made near the mouth of the Thames it became alkaline early in April; the alkalinity increased to a maximum at the end of June and then began to decline. It seems probable that this increase of alkalinity will cause sea water to take up more carbon dioxide, and that this increase, used up by the growing organisms, will lead to the production of more oxygen.

The fact that in still water oxygen is very slowly liberated is not of much practical importance, because sea and estuary water are seldom still, and even gentle stirring greatly increases the rate of loss of oxygen by sea water. When waves are breaking, the excess of oxygen is very rapidly got rid of; in fact, the amount dissolved may fall below the saturation point. As Butler and Coste point out, the seas during the spring, and perhaps during the autumn also, are a great natural factory where free oxygen is produced on a scale which,

<sup>1</sup> *Plankton* is a collective name for all the forms of floating or drifting organic life found at various depths in the ocean, or, by extension, in fresh water (N.E.D.). Phytoplankton is the vegetable part of the plankton.

<sup>2</sup> *Linnean Society's Journal—Botany*, xlv (1922); *Nature*, March 31st, p. 48.

<sup>3</sup> *Biochemical Journal*, xvii, No. 1 (1923), p. 43.

having regard to the relative areas of sea and land, may conceivably exceed that of land vegetation. "It is tempting," they continue, "to speculate on the part played by oxygen thus liberated in producing the salubrity attributed to sea air." The seas breaking on the shores "are liberating their surcharge of oxygen in its most active state, and it is seen that not the chemist, or the marine biologist alone, is interested in a phenomenon which has for its theatre of operations vast tracts of oceans and the littorals of continents."

However this may be, the observations are undoubtedly very interesting, though they fail to account for the rapid fall in vegetation and in the surcharge of oxygen during July and August in these latitudes. The sun is above the horizon as long in July as in May, and there is a rise in the temperature of the sea which is believed to favour photosynthesis.

#### THE TRAFFIC IN DANGEROUS DRUGS.

REPORTS recently issued by the League of Nations relevant to the enforcement of the International Opium Convention of 1912 indicate that that body is "making haste slowly" with the mondial control of drugs of addiction. The Advisory Committee which met for the fourth time in Geneva in January was specially invited to deal with a suggestion emanating from the Assembly of the League—namely, to boycott all exports of the scheduled "dangerous drugs" from non-adhering countries such as Turkey, Persia, Switzerland, and the Argentine. Further consideration of this suggestion, however, indicated that there were lions in the way. It was pointed out that a not impossible result of its adoption might be to give to India a virtual monopoly of the legitimate export trade in opium and that the total amount of the world's production of opium might even be thereby increased. Moreover, as the recalcitrant countries were reported to be showing signs of grace—indicative of a willingness to ratify the Convention—the further consideration of this question was postponed till the next meeting in May, when it was hoped a convenient occasion for a review of the whole situation would be afforded. The system of requiring licences or certificates in respect of all imports of the drugs in question, which is but a corollary to the stipulations of the Opium Convention, has yet been adopted by only twenty-seven of the fifty-one States which are members of the League of Nations; and a large number of the member States have neglected to furnish the statistics, which they were requested by the Council to supply, showing the amount of opium, morphine, heroin, and cocaine produced, consumed, imported, and exported by each country. A Joint Subcommittee of the Health and Opium Committees has given further consideration to the difficult problem as to what amount of the several drugs may be deemed to be legitimately required for internal consumption in each country, and also to the best methods of arriving at the quantity of each used for medicinal purposes. A previous attempt by the Health Committee to solve the question yielded inconclusive results. The Joint Subcommittee, after a detailed discussion, resolved, apparently by a majority of three to one, that the medical and pharmaceutical use of these drugs should be considered the only legitimate use, and that medical opinion did not regard the use of opium as a stimulant, even in tropical countries, as legitimate. The Opium Advisory Committee in its report to the Council recorded with particular satisfaction the participation of the United States in its labours by the nomination of a representative to act in "an unofficial and consultative capacity." American opinion has recently been reawakened on the subject of the drug traffic by a resolution of the House of Representatives, introduced by Mr. Porter, requesting the President to urge upon certain Governments "the immediate necessity of limiting the production of habit-forming narcotic drugs and the raw materials from which they are made to the amount actually required for strictly medicinal and scientific purposes." In this resolution the Governments of Great

Britain, Persia, and Turkey are specifically referred to as regards the cultivation of the opium poppy, and Peru, Bolivia, and the Netherlands as regards the production of coca. Evidence recently given by medical men and social workers before the Foreign Affairs Committee of the House of Representatives has emphasized the great increase in the illicit use of habit-forming drugs in the United States of recent years—more especially of heroin—and the depravity and crime attributable to this nefarious traffic.

#### THE THEORY OF VISION.

IN a paper read a short time ago before the Royal Society of Arts Dr. F. W. Edridge-Green contested the orthodox theory of vision put forward by von Kries and others, and very widely accepted, which supposes that the rods in the retina are sensory cells like the cones, and that, whereas the cones are used in the daytime for the appreciation of colour, the rods are used at night, when the light is so dim that colour cannot be appreciated. Dr. Edridge-Green disagreed with this duplex theory, as it is called, and held that there was no evidence that the rods are sensory. He maintained that they are accessory and are the sensitizers of the cones, secreting the visual purple which is changed by light. There was, he thought, good reason to believe that the means by which light stimulated the nerve endings was through a photochemical reaction; the decomposition of a photochemical film, sensitized by the visual purple, stimulated the ends of the cones, and a visual impulse was set up which was conveyed through the optic nerve fibres to the brain. He maintained that the function of the rods was to regulate the supply of visual purple to the film in accordance with the amount of light falling upon the eye, and expressed the opinion that this theory of vision not only explained all the known phenomena, but enabled various other facts to be predicted. The theory which supposed the rods to be percipient elements for perception in dim light, while the cones were the percipient elements in daylight, he believed to be irrational, for it was difficult to conceive an element stimulated by the decomposition of a photochemical substance which was excited by weak light and not more strongly excited by a brighter light. This theory was supported by what he described as misstatements. One of these was that certain animals had only cones and others only rods; he had made numerous examinations but had never found any animal with only cones or only rods. The creature which was most commonly said to have cones only was the tortoise, but the rods in the retina of the tortoise were as clearly defined and distinct as in the human retina. It was also said that the periphery of the retina was colour-blind; this was not the case when colours of sufficient intensity were used, as anyone could test for himself with a red lamp, which he would find could be seen as red to the extreme periphery. The statement that the eye was totally colour-blind in dark adaptation was also ill founded, as was proved in a masterly paper Burch had communicated to the Royal Society (*Proceedings*, vol. 763, p. 199). Yet another misstatement was that the Parkinje phenomenon and the recurrent image were not found at the fovea. Altogether it was difficult to comprehend how vision could occur on this theory. How were the central connexions in the brain arranged in order to obtain localization, with a large scotoma in the most important part of the field of vision? Professor E. H. Starling, who presided, said that Dr. Edridge-Green's theory was consistent with known physiological facts, and was therefore worthy of thorough investigation. The orthodox theory was brought forward with great authority by men of the intellectual magnitude of von Kries and others, but its weight of authority was really a disadvantage, because it caused the theory to be accepted unquestioningly. All such theories should be divested of the authority of the men who gave them birth and the facts regarded *de novo*. By physiological facts he meant such as could be observed sometimes on animals, more often on oneself.

## OXFORD OSLER MEMORIAL.

CONSIDERABLE progress has been made in the plans for a memorial to Sir William Osler in Oxford, where he was for fifteen years Regius Professor of Medicine. At a recent meeting of subscribers, Sir Archibald Garrod, speaking on behalf of the Committee, put forward certain proposals which he said had the entire approval of Lady Osler, as well as of other friends from whom letters had been received. The first proposal was to place in the University Museum a bronze portrait plaque of Sir William Osler, a replica of that made for the Medical Faculty of Maryland by Vernon of Paris. A second proposal was to establish an Osler Memorial Medal in bronze, to be awarded every five years to a graduate of the University of Oxford who has made some distinguished contribution to medical science, learning, or practice. It was decided to use the remainder of the sum contributed for an Osler Travelling Fund for the propagation or acquisition of medical knowledge or for medical research. The intention is to invest the fund and to use the interest to assist teachers of the Medical Faculty to travel for these purposes. The sum in hand, however, is not adequate, amounting only to about £1,700, and further subscriptions are invited. The motion to adopt these proposals was seconded by Major-General Sir Frederick Bradshaw, K.C.B., A.M.S.; it was carried without dissent, and the Executive Committee, which consists of Sir Herbert Warren, President of Magdalen College (chairman), Sir Archibald Garrod, F.R.S., Sir Charles Sherrington, P.R.S., Professor Arthur Thomson, Mr. Dodds-Parker (honorary treasurer), and Professor J. A. Gunn (honorary secretary), was empowered to carry the proposals into effect, and to negotiate the necessary arrangements with the University. Further subscriptions should be sent without delay to Mr. A. P. Dodds-Parker, 2, Holywell, Oxford.

## CONJUGAL TUBERCULOSIS.

DR. PAUL ROUSSEL has issued an interesting account of the statistical information he has obtained from an inquiry into the frequency of tuberculous infection amongst families of the poorer classes at Nancy, and in particular with regard to conjugal tuberculosis.<sup>1</sup> He prefaces the account of his own observations by a review of the results and conclusions of others as recorded in the literature, and a discussion of his own conclusions on the basis of the immunity afforded by mild, repeated infection during childhood. His statistics concern a homogeneous working-class group, living generally under bad social conditions, which has come under the care and supervision of the Villemin Dispensary since its foundation in March, 1920. They comprise altogether 423 families in which either one or both of the married persons were suffering from tuberculosis. In 211 cases the husband alone, and in 163 cases the wife alone, was affected, while in 49 cases both partners were attacked. Examining these 49 cases of concurrent disease, he found that in 27 of them the possibility of conjugal infection could be dismissed. There remained, then, 22 instances to be explained, and in these direct contagion appeared certain or highly probable in 14 and possible in 8. Taking the former figure, it is seen that the proportion of cases of conjugal transmission of tuberculosis may be given as 5.2 per cent. The smallness of this estimate shows how comparatively slight is the danger of such transmission. But, further, it was found that of these 22 accepted cases no fewer than 15 were latent. In fact, in only 4 individuals out of 423 married couples did a rapid type of disease result from the intimacy contingent on the married state. Of the 22 cases referred to, it is interesting to note that in as many as 18 of them the infection was from husband to wife. The length of cohabitation before the disease manifested itself was from six months to twelve years and in 4 instances it did not commence till after the death of the primarily infected partner. Dealing only with open cases of tuberculosis having a positive sputum, the proportion of cross-infections was raised to 11.56 per cent.

<sup>1</sup> *La tuberculose conjugale: contagion et mariage.* By Dr. Paul Roussel. Paris: A. Maloine et Fils, 1922. (Illo.), 8vo. pp. iv + 160. Fr. 10 net.)

Excluding 85 families who were without offspring, it was found that in 25.02 per cent. of general cases and in 37.59 per cent. of open cases the children were tuberculous. These figures are probably on the low side, as simple cases of adenopathy were not included, unless they were accompanied by definite evidence of tuberculosis in the lungs or elsewhere. Summing up, then, it may be said that conjugal infection is uncommon, even in the poorer classes, and that when it does occur it is generally only after a lengthy period of cohabitation, that the wife is more likely to suffer than the husband, and that the disease usually runs a benign course. The danger to the children, however, is so serious that, in the event of the marriage being fruitful the very greatest care must be exercised by a rigid—albeit humane—system of prophylaxis to prevent their early and fatal contamination.

## HOSPITAL ALMONERS.

THE Institute of Hospital Almoners carries on a branch of social work of which the late Sir Charles Stewart Loch was the founder; it has its offices in the house of the Charity Organization Society, Denison House, 296, Vauxhall Bridge Road, S.W. The institute selects and trains suitable candidates for the work of hospital almoners, grants certificates and diplomas, keeps a register of trained almoners, and co-operates in preventing the abuse of hospitals and in promoting health amongst the industrial and poorer classes. The report for 1922 points out that the sphere of activities of a hospital, a general hospital in particular, is wider than might at first sight appear, for the welfare of the patient is influenced by the educational and public health authorities, by war pensions committees, and many other organizations. Further, the records of the almoners on the social and economic conditions of the patients are proving of statistical value, and during the past year an almoner has been engaged by the Medical Research Council for special investigations into the records of the social work done during the past seven years at St. Thomas's Hospital and the neighbouring Lying-in Hospital in York Road. Evidence of the care displayed in selection is afforded by the fact that over 40 per cent. of the candidates who apply for training are rejected as unsuitable. The training lasts for at least two years, and includes four months' work in an office of the Charity Organization Society in London, and nine months under the direction of the Ratan Tata Foundation of Social Science and Administration; there follows eleven months' work under an almoner at a hospital training centre, two of them being spent in visiting other hospitals, and one in practical work outside the hospital—for example in infant welfare centres, rescue homes, and tuberculosis clinics. The fee for the training, covering the whole course of lectures and instruction, is 40 guineas. In the membership of the institute are included the almoners of a number of the larger hospitals in London and the provinces. The President is Sir Napier Barnett, M.D. The report lays stress on the special qualifications required in an almoner, such as a generous education, a wide outlook, and broad sympathies, so that she may become "the link between the hospital and the home." This view of the almoner's duties is emphasized by a quotation from an article in *The Hospital*, stating that "too much attention was at first directed merely to one of the almoner's functions—the exclusion, namely, of the unsuitable recipient of charitable help, but this . . . has now fallen into its rightful place as a comparatively subordinate matter." The council of the institute finds it difficult to estimate what demand there will be for almoners two years hence, but it feels that not enough women are entering upon the work to fill the vacancies that are likely to occur.

## EPIDEMIC HICCUP.

FOLLOWING the recognition of encephalitis lethargica attention has been called, especially in France, to epidemic hiccup. Its etiology is obscure, but epidemiological and clinical data suggest that it is related to encephalitis lethargica, as it often

occurs in the course of that disease; the two appear contemporaneously in the same districts, and the diaphragmatic spasm may be regarded as a manifestation or variant of the myoclonic form. Rosenow, of the Mayo Clinic, who in 1921<sup>1</sup> produced spasms of the diaphragm in monkeys and rabbits inoculated intravenously and intracerebrally with a streptococcus isolated from pus obtained from the tonsils of patients with epidemic hiccup, now carries this research farther.<sup>2</sup> Intracerebral injections with dead streptococci and filtrates of cultures were found to give rise to spasm of the diaphragm, the duration of symptoms being shortest after the injection of filtrates, longer after the introduction of dead streptococci, and most persistent after the inoculation of the living organisms. The streptococcus is similar to the diplo-streptococcus, which he described in 1916 in encephalitis lethargica and recently identified microscopically in or adjacent to the lesions in a series of 21 cases of epidemic encephalitis<sup>3</sup>; it belongs to the pneumococcus-streptococcus group of organisms normally present in the upper respiratory tract. It was recovered from the experimental animals and produced spasm of the diaphragm and other muscles in further animals but symptoms of lethargic encephalitis became more frequent and diaphragmatic spasm less common with the number of animal passages; it therefore appears that the peculiar localizing power or *neurotropic* property of the hiccup streptococcus is acquired and perhaps a phase in the life cycle of the pneumococcus-streptococcus group of organisms. The symptoms were permanently controlled by anti-encephalitis serum in an animal inoculated by a strain of streptococcus which was specifically agglutinated by the serum. The central nervous system of the animals showed perivascular infiltration, in early stages with leucocytes, later with mononuclear or plasma cells. The streptococcus produces a chemical substance, and the persistence of hiccup depends on the continued production of this substance in the central nervous system or elsewhere. That the impulse producing the spasm is of central origin is shown by the observation that heroin, a depressant of the respiratory centre, controls the spasms. This may possibly be of service in practice, for morphine has generally been found to be the most successful of the numerous drugs tried in obstinate hiccup, and it has been stated that in epidemic hiccup nothing is effectual in stopping the paroxysms, though pressure upon the eyeballs has been said to be successful.

#### PLUMBISM AND LEAD PAINT.

In 1911 Home Office Departmental Committees recommended the total prohibition of the use of paint containing more than 5 per cent. of its dry weight of a soluble lead paint except for certain special purposes. At the third conference of the International Labour Organization of the League of Nations, held at Geneva in October and November, 1921, a draft convention was presented to which the British Government took exception, stating that it had reason to doubt the conclusions reached by the committees in 1911, and was making further inquiries. The conference eventually adopted almost by unanimity a convention inviting the various countries represented to bring into force, six years from the date of the conference, regulations prohibiting the use of white lead or lead sulphate for interior painting, except in the case of railway stations and factories where lead painting may be considered necessary by a competent authority. The British inquiry referred to was committed to another Home Office Departmental Committee presided over by Sir Henry Norman, M.P. This committee has just presented its report. The committee was instructed to examine the question of the danger to the health of workers in the painting trade, and inquire into the questions of comparative efficiency and cost. The committee reports that it is satisfied that for outside

painting and for certain kinds of internal painting there is at present no efficient substitute for lead paint, and that the prohibition of lead paint for certain purposes is likely to involve an increase of cost. The committee at the same time recognizes that the statistics of lead poisoning arising from lead paint, in its production and in its use, are sufficiently serious to make it desirable to limit its employment as far as possible, and to make it subject, where used, to statutory regulations; the British regulations for trades concerned in the production of lead and its use as a glaze in pottery have worked well, and there are none superior to them in any country. New regulations are necessary only for painting and the rubbing down of old paint. As regards white lead and lead sulphate, and paint bases containing these substances, the committee considers that the needs are adequately met by the agreement reached at the Geneva Conference and subsequently embodied in the convention adopted there. Legislation will be necessary to give effect to the principles contained therein, and the committee agrees that the prohibition of the use of white lead and lead sulphate for internal painting should not come into force until 1927 as the convention prescribed. It is suggested, however, that regulations to deal with the continued use of lead paint should be brought into force at the earliest possible moment. An important practical point is that the committee accepts the view that lead poisoning among painters is almost entirely caused by dust produced in dry rubbing down, and that dry rubbing down is no longer necessary and can be replaced by a damp process. It therefore advises that the dry rubbing down process should be prohibited, and expresses approval of a draft code of regulations drawn up by the Home Office in collaboration with representatives of the Painters' and Decorators' Industrial Joint Council, and unanimously accepted by both sides of that Council and also by the National Federation of Building Trades Employers.

#### THE ROYAL SOCIETY OF MEDICINE.

We have already called attention to the institution by the Royal Society of Medicine of an order of Associates. The action of the Society seems to have escaped the attention of some of those eligible, for we understand that very few applications have been received. Any qualified man or woman, whether British or otherwise, is eligible to be elected an Associate within five years of obtaining a first professional qualification. The annual subscription is three guineas, but there is no admission fee, and an Associate who has paid three annual subscriptions does not pay an admission fee on election to the Fellowship. Associates are entitled to all the ordinary privileges of Fellows, but may not borrow more than one volume at a time, and do not receive the *Proceedings* gratis.

THE Chartered Society of Massage and Medical Gymnastics which was formed by the amalgamation of the Incorporated Society of Trained Masseuses and the Institute of Massage and Remedial Gymnastics (Manchester), received its charter in June, 1920, and numbers amongst its objects the improvement of the training, education, and professional status of persons engaged in the practice of massage, medical gymnastics, electrotherapeutics, and kindred methods of treatment; the promotion for such persons of a uniform curriculum and standard of qualification, and the maintenance of registers of persons qualified in the opinion of the society to practice or teach the practice of these forms of treatment. Members are required not to undertake any cases of massage except under the direction of a registered medical practitioner; not to advertise except in recognized medical and nursing papers; not to sell goods to patients in a professional capacity; and not to accept secret commissions on the sale of goods. The society has now issued its first register of members covering the period from July, 1920, to September, 1922; it contains the names and addresses of over 4,500 masseuses and masseurs in the United Kingdom and abroad. The possession of additional certificates (as in medical electricity and gymnastics) is indicated, and a place index adds considerably to the usefulness of the main register. There are separate sections for masseuses and masseurs.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons adjourned on March 30th until Monday, April 9th. The following are notes of the business of medical interest done during the last three days before the adjournment, and of some other matters, which we were compelled to postpone last week owing to pressure on space.

### The Cost of State Relief.

Sir Walter de Frece asked, on March 20th, the aggregate amount per head of the population now distributed by the State for various services and insurances. The Chancellor of the Exchequer replied that the amounts per head of the population distributed in 1922-23 in Great Britain on the services stated were estimated to have been approximately as follow:

	s.	d.
Unemployment benefit	...	19 6
Poor Law relief	...	19 0
Old age pensions	...	10 0
Service and kindred pensions, including the pensions of school teachers and the police	...	13 6
War pensions	...	30 0
Health insurance benefits	...	11 0

The figures included not only money provided from taxes and rates, but also, in the case of the health and unemployment insurance schemes, contributions by employers and employed. Separate figures were not available for uncovenanted unemployment benefit.

### Dangerous Drugs Regulations.

In reply to Dr. Molloy, on March 29th, the Home Secretary, Mr. Bridgeman, said he proposed to make a regulation revoking No. 1 of the amending regulations made on October 2nd, 1922, under Section 7 of the Act. [This provided for the insertion of the words: "The prescription shall not be given for the use of the prescriber himself."]

### Imports of Dangerous Drugs.

The Home Secretary, on March 28th, gave the following statistics of the importation of dangerous drugs in the years 1920 and 1921, mentioning that the only figures for 1920 were those of the Customs' officials, and were incomplete. For 1921 the figures of return prepared by the Home Office were available.

In 1920 there were imported into the United Kingdom 423,530 lb. of opium, 320 oz. of morphine, and 7,227 oz. of cocaine. These amounts were made up by consignments from various foreign countries and British possessions as follows:

Opium.—France, 130 lb.; Turkey (European), 210,377 lb.; Turkey (Asiatic), 122,713 lb.; Persia, 3,910 lb.; other foreign countries, 2,370 lb.; British India, 82,956 lb.; Hong Kong, 820 lb.; other British possessions, 244 lb.

Morphine.—United States of America, 320 oz.

Cocaine.—Germany, 2,368 oz.; France, 2,083 oz.; Switzerland, 1,000 oz.; Peru, 1,424 oz.; other foreign countries, 352 oz.

In 1921 the total amounts of these drugs imported were: Opium, 58,161 lb.; morphine and morphine salts, 1,100 oz.; cocaine and cocaine salts, 24,653 oz. The amounts consigned by various countries were as follows:

Opium.—Greece, 8,348 lb.; Italy, 339 lb.; Persia, 1,246 lb.; Spain, 176 lb.; Switzerland, 848 lb.; Turkey (European and Asiatic), 45,079 lb.; other countries, 2,125 lb.

Morphine and Morphine Salts (including morphine content of preparations and admixtures).—France, 1 oz.; Switzerland, 870 oz.; Turkey, 229 oz.

Cocaine and Cocaine Salts (including cocaine content of preparations and admixtures).—France, 19,955 oz.; Germany, 2,073 oz.; Greece, 61 oz.; Holland, 2,544 oz.; United States of America, 30 oz.

**Mortality from Cancer.**—Dr. L. G. Molloy asked, on March 28th, what was the death rate from cancer in Great Britain at the present time; what was the death rate from this disease in the previous four decades; what proportion of deaths from all causes other than accident or violence were due to this scourge; and what financial provision was made by His Majesty's Government towards assisting those engaged in fighting this plague by endeavouring to ascertain its causes and the best means of combating its ravages. Mr. Chamberlain replied that the standardized death rates from cancer in the four decades 1881-1893, 1891-1900, 1901-1910, and 1911-1920 were respectively 610, 761, 867, 966, and 1,007 per million of the population. In England and Wales the cancer deaths during the above decades represented 3.2, 4.3, 6.1, and 8 per cent. of the total deaths from all causes other than those due to accident and violence. The promotion of cancer research was among the purposes for which an annual subsidy was made by Parliament to the Medical Research Council, and the Council from time to time made grants in aid of investigations which might bear on the incidence, causation, and treatment of cancer. The Council also had in its charge a quantity of radium salt belonging to

His Majesty's Government, and with this had organized an investigation into the treatment of cancer by means of radium in ten different hospital centres in this country. Dr. Molloy was no doubt aware that an extensive research into the causes of the disease had for some time past been undertaken by the Imperial Cancer Research Fund.

**War Pensions Act Amendment Bill.**—Mr. Frederick Roberts, on March 21st, introduced on behalf of the Labour party a bill to provide that where an ex service officer or man, after leaving the service, was found suffering from tuberculosis, neurasthenia, or any other disease or incapacity reasonably attributable to war service, acceptance for such service should be taken as proof of attributability unless or until the contrary was proved. In other words, the measure proposes that pensions should be granted unless the Ministry of Pensions can prove that the illness be not attributable to war service, the onus of proving the negative to be placed on the department. The bill was read a first time.

**Assessment of Pensions.**—Mr. Ponsonby asked, on March 22nd, whether the Minister of Pensions had received complaints from the Handsworth branch of the British Legion as to cases in which local medical boards were alleged to have contradicted the decision of the Pensions Appeal Tribunal when it had been in the applicant's favour, and whether the Appeal Tribunal could, at the time of the hearing of an appeal, assess the disability so that the Ministry of Pensions could make the award accordingly. Major Tryon said that the complaint was based upon a misapprehension, for decisions of the Pensions Appeal Tribunal were invariably accepted. An assessment tribunal might, in confirming the finality of the award, increase or reduce it, or might simply decide that the case was not ripe for final decision. This did not necessarily mean that the tribunal disagreed with the rate at which the man's disablement had been assessed, and steps were being taken to make this clear in announcing decisions of this nature. Major Tryon has stated that, in cases of disability accepted by the Ministry as due to war service, pension was always awarded at the rate appropriate to the degree of disablement certified by the medical board by whom the man was examined. If a claim was based on deterioration the man was referred for examination by a medical referee, not for an assessment for pension purposes, but for a preliminary expression of opinion on the merits of the claim. If the medical referee reported the claim the man was then examined by a board, whose assessment was accepted and acted upon, whether higher or lower than the estimate given by the medical referee. The Ministry granted an allowance to carry on. The total number of four-year cases submitted in Great Britain and Ireland for consideration for final award under Section 4 (2) of the War Pensions Act, 1921, was 48,183, and the percentage recommended for final awards was 58.4. The total number of medical practitioners on the panel from which members of medical boards for the Glasgow area were drawn was 172, of whom 85 per cent. were ex-service doctors. The number of pensions to officers is approximately 2,000, and the annual value of about £3,100,000. During the last year, 1923, some 30,000 pensions to officers were granted. The medical re-examination as required by the warrant. Of these, 67 per cent. remained unaltered or were increased, while 33 per cent. were decreased or terminated. The result of these changes represented a net decrease in the annual value of the awards reviewed of approximately £345,000. The first part of the Handbook of War Pensions is now ready.

**Pensions Appeals.**—Major Tryon has stated that approximately 1,400 appeals by officers and 70,000 appeals by other ranks were decided by the Entitlement Tribunal during the two years ended December 31st, 1922. The percentages of these appeals allowed were 48 per cent. and 56 per cent. respectively. Of awards which have become final the Pensions Department up to December 31st, 1922, made 153,000 of nil or less than 20 per cent., and 40,000 of 20 per cent. and over. Up to the same date approximately 13,050 appeals against final awards were decided by the Assessment Appeals Tribunal. In 62 per cent. the final award was confirmed unaltered; in 19 per cent. the final award was confirmed at a higher assessment; and 19 per cent. were set aside by the tribunal. The number of cases within each of the last six months in which medical advisers of the Ministry of Pensions have declined to accept the mental derangement of applicants as due in any way to or exaggerated by war service were: September, 34; October, 16; November, 57; December, 34; January, 52; and February, 58. The Minister said that he was satisfied that this type of case received most sympathetic consideration. There was, moreover, statutory right of appeal to a tribunal independent of the Ministry.

**Service Patients in Asylums.**—Captain Craig stated, on March 20th, in reply to Mr. Frederick Roberts, that by arrangement with the Board of Control a systematic inspection of all "service patients" in asylums had been carried out for some time past by medical inspectors of the Ministry of Pensions. Considerable progress had

been made in the exercise of his powers under the Lunacy laws, insisted on the removal of a patient against the advice of a medical superintendent, it was the practice to point out to the responsible relatives that, should application be made for the readmission of the patient to the asylum (which experience showed frequently happened), the question of reissuing family treatment allowance must be considered afresh. This was a reasonable procedure, which was exercised with the greatest discretion, and solely in the interests of the patient's treatment, and in no way conflicted with the provisions of the Lunacy Act. Asked the cost of maintenance of

There is at present no intention of discontinuing medical benefits in Dublin, which are necessary to meet the needs of persons there. Constant attention is paid to the possibility of making economies, but it is not probable that any substantial saving can be effected.

## HEALTH OF THE ROYAL AIR FORCE.

The public anxiety about the condition of our Air Force defences may have attracted the attention of medical men to what its medical service has been doing, and the second Report on the Health of the Royal Air Force for the Year 1921, submitted by Air Commodore D. Munro, Director of Medical Services, may therefore be said to have appeared at an appropriate moment.

This report is on the same general lines and of almost exactly the same length as the previous and first report, for the year 1920, which was fully noticed in the *BARRIST MEDICAL JOURNAL* of December 31st, 1921 (p. 1122); but statistics relating to the health of the Royal Air Force in India which were not included in the first report are now given. It is admitted that the health figures for India are not satisfactory, and this is ascribed to the inexperience of both officers and men in the precautions and sanitary measures necessary for the preservation of health in the tropics, to the presence of men new to tropical climates, living under camp conditions in several of the stations, to the disposing influence of heavy physical work for long hours, and in some units to lack of trained unit sanitary squads, the provision of which, it is hoped, will be supplied in time. Disinfection has not been so thoroughly carried out as it should have been, apparently from lack of disinfectors, and flies have therefore been unnecessarily numerous. The water and food supplies have been good, but the fly-proofing of some of the kitchens proved to be unsatisfactory on account of the large mesh of the gauze employed. In spite, however, of the greater incidence of sickness in India than elsewhere it is satisfactory to learn that the health of the total force shows a well marked improvement, and that the death rate (excluding the twenty-four deaths in the R.38 disaster) for 1921 works out at 3.9, as compared with 4.4 per 1,000 in 1920.

Efforts made to reduce venereal disease have been successful in lowering the total case incidence in the Royal Air Force from 49.6 in 1920 to 36.1 per 1,000; the prophylactic measures adopted have been educational, recreational, and preventive; all men acquiring venereal disease are questioned by their medical officer as to the measures of prophylactic disinfection adopted, and, according to the statement given, are recorded as "used properly," "used improperly," or "not used," the first term being applied only to instances in which the procedure was carried out within two hours of exposure. The case incidence per 1,000 of scabies fell from 32.2 in 1920 to 14.3, and the average duration of each case from 12.3 to 10.3 days, but this is still too long; the case incidence of the group of affections included under the heading of "upper air-passage infection" was slightly lower, but that of influenza was 26.4, as compared with 12.7 per 1,000 in 1921, chiefly from a mild type of the disease.

Graphs of the incidence of sandfly fever show a well marked reduction in Iraq for 1921, where experience shows that the severity varies so much from year to year that it is impossible to say how much the lowered case incidence was due to the prophylactic measures. The disease is usually more frequent and severe in new arrivals. Research carried out at Malta by the R.A.F. bacteriologist led to the isolation, from cases of the disease, of an organism very similar to *Leptospira icterohaemorrhagiae*; but, as transmission of the disease in its characteristic form to men or animals has not been obtained, no specificity is claimed for the spirochaete. At Bagdad blood examinations of 70 cases showed the same features as in Malta—namely, a leucopenia for the first three to five days, followed by a leucocytosis. By routine treatment consisting of starvation, purgation, and doses of aspirin, the duration of disability was shortened. In sandfly fever the early leucopenia is accompanied by a relative lymphocytosis; this is of value in making a diagnosis from the effects of exposure to the direct, or less often the indirect, action of the sun's rays. For cases of a comparatively mild nature, for which the only terms in the Official Nomenclature of Diseases—heatstroke, sunstroke, and insolation—are not warranted, the term "heat exhaustion" has now been introduced; the older names can therefore be reserved for cases with a sudden onset, usually accompanied by hyperpyrexia, and with or without cerebral symptoms and unconsciousness. The clinical picture of heat exhaustion

includes comparatively slight fever, dizziness, intense headache, pain in the back and limbs, and varying degrees of collapse; it must be distinguished not only from sandfly fever, but from sudden pyrexias which often appear to be due to constipation.

The nomenclature of functional nervous disorders has also been revised in the light of modern psychological research: the term "psychosis" is confined to the diseases designated in the official nomenclature as "mental diseases," with the partial exception of psychasthenia. The term "psychasthenia" is restricted to the clinical entity described by Janet, which is mainly characterized by volitional defects and obsessional ideas or impulses; when the latter are antisocial, psychasthenia may fall under the heading of a psychosis, otherwise it belongs to the next group. The psychoneuroses are disorders of function other than the psychoses that are purely psychic in origin, and are subdivided into: (1) hysteria, including suggestion neurosis and conversion hysteria; (2) neurasthenia, characterized by symptoms of mental and physical fatigue; (3) anxiety neuroses with "nervousness," depression, insomnia, emotional instability, lack of concentration, defective memory, with or without tremor and tachycardia; (4) border-line cases with, in addition to the symptoms of anxiety neurosis, so much intellectual impairment that the patient is incapable of looking after himself and his affairs properly. The form of psychoneurosis most commonly met with in the Air Service is the anxiety neurosis which is generally speaking associated with flying stress, whereas neurasthenia specially occurred as the result of arduous administrative responsibilities and lack of physical exercise.

The section on physical efficiency shows that all officers are examined yearly, and the results of both the routine clinical examination and of the physical efficiency tests compared with the previous records; the effects of climate and flying can thus be estimated. The importance of this is that an officer who, after much flying in India or Iraq for a year or more, remains physically fit for full flying duties may be assumed to be well adapted to withstand the strain of war flying.

This report, with its charts and numerous tables, contains much interesting information, and bears witness to the energetic spirit of the medical service of the Royal Air Force.

## England and Wales.

## WELSH NATIONAL MEDICAL SCHOOL.

The Privy Council has written another letter adhering to its view that the constitution recently submitted for the Welsh National Medical School is unsuitable. It is pointed out that the principal objects of any scheme should be:

1. To provide the organization which will give the school the best opportunity of developing successfully into a first-rate centre of medical teaching and research.
2. To give the school a genuinely national status.
3. To recognize the special interests of the Cardiff University College in the school.

The Privy Council finds that in the scheme submitted the attempt to harmonize these objects has resulted in neglect of the first, though from the point of view of the interests of university education it is undoubtedly the most important of the three, and in giving less than its due weight to the second. The Council considers that it will not be a short or easy task to build up out of the existing material a complete and well equipped school, and that as a matter of common prudence care should be taken that the mere machinery of government should interpose no unnecessary obstacles. The proposal actually made, however, is for a division of controlling functions between no fewer than four bodies—the University Council, the Advisory Board of Medicine of the University, the College Council, and the College Board of Medicine. The school's chances of success would, it is considered, be far greater under the simpler method of administration recommended by the recent Royal Commission. The reasonable claims of Cardiff University College could be met, not by bringing within its administration an institution whose government it is desired to put on a broad national basis and for which separate financial provision seems advisable, but by giving it a very substantial representation on the governing body of that institution. The Cardiff College would gain by being relieved

<sup>1</sup> Report on the Health of the Royal Air Force for the Year 1921. Air Publication 924. Published by H.M. Stationery Office. 1923. (12p. 20; 5 charts, 32 tables. Price 5s. net.)

of a partial and ill defined responsibility for an institution the ultimate control of which no one proposes to give to it, and the School of Medicine, if established as an independent unit, would, to its great benefit, receive a status and form of government which would be simple and easy to understand; its administration, under the University, would be in the hands of a single authority with an undivided interest in the furtherance of medical education and research.

#### NURSING AND MIDWIFERY EXHIBITION.

What is probably the largest Nursing and Midwifery Exhibition yet held in this country has been open during the present week at the Central Hall, Westminster. It is the thirteenth of an annual series of such exhibitions, and, thanks to the larger space available on this occasion, it includes for the first time a hospital section.

A model operating theatre has been installed, various firms supplying the equipment, model offices for a matron and a hospital secretary, and a model ward kitchen. The British Red Cross Society has given demonstrations in this section of the treatment by light baths and electrical apparatus administered to service pensioners and others, and the St. John Ambulance Association has demonstrated its various activities. The remainder of the section is occupied by an exhibition of coloured anatomical models, lent by the Science Museum at South Kensington, some pathological exhibits from the Cancer Hospital and the Chelsea Hospital for Women, and various charts, photographs, and radiographs. The main exhibition comprises well over a hundred trade stands, chiefly displaying various modern requisites for the sick-room, the lying-in chamber, the nursery, and the nurse's personal outfit. In addition to most of the familiar foods and toilet preparations, such things were noticed as a "chiro-pody clinic," and an improved incubator, or "thermostatic nurse," for premature or sickly infants, in which the electrical heating of the chamber is automatically reduced day by day so as to prepare the child for the outer temperature. We were informed that these appliances can now be hired in an emergency.

In association with the exhibition a four days' conference has been held. The programme, arranged by a committee of matrons of the principal hospitals, included such subjects as district nursing, the place of the midwife in the public health scheme, dental care and food values, venereal diseases, and the conditions of nursing in certain European countries. The exhibition closes to-day (Saturday).

#### LIVERPOOL ROYAL INFIRMARY.

The annual meeting of the subscribers of the Royal Infirmary took place on March 21st, with the President, Mr. Thomas H. Bickerton, consulting ophthalmic surgeon, in the chair. The honorary treasurer's report showed that £14,837 had been received as legacies during the past year, and £2,665 represented a grant from the Voluntary Hospitals Commission. The result was that on the year's working of the institution there was an excess of—total income over total expenditure—£5,852. Unfortunately, owing to a further decrease in annual subscriptions, the ordinary income showed a deficit of £11,214. The building of the new nurses' home was progressing rapidly, towards the cost of which £28,000 was available, and an urgent appeal for the amount outstanding—£9,000—was made by the treasurer, who commented upon the extraordinary number of legacies the Infirmary had received during the past year. The number of in-patients was 4,477, an increase of 324 over the preceding year. The number of out-patients that attended the various departments was 26,821.

Mr. Bickerton, in moving the adoption of the report and financial statement, gave an interesting historical sketch of the Royal Infirmary, which was instituted in 1749, up to the present time. Henry Park was one of the first surgeons appointed, and three successive generations of Bickersteths covered the whole period from 1749 to the present day. During these years nursing had developed from the Sairey Gamp type of nurse to the present efficient trained nursing sister. Previous to 1862 convalescents were frequently used to wait on the other patients, and not infrequently the so-called nurses were discharged for "want of steadiness." He made a special appeal on behalf of the new nurses' home, which was essential for their health and happiness. The public should not forget what an important part nurses played in maintaining the health and administering to the sick in all ranks of the community. Mr. G. Thurstan Holland, having resigned office owing to the age limit, received the warm thanks of the meeting for his services as honorary radiologist during the past eighteen years, and (as we announced last week) he was appointed honorary consulting radiologist. Mr. Bickerton's address was much appreciated, and he was unanimously re-elected president for the ensuing year.

## Scotland.

#### EXCHANGE OF PROFESSORS.

An interesting development in the relations between Edinburgh and some of the American medical schools has been initiated by a visit of Sir Harold Stiles to Boston. Sir Harold Stiles, who is Professor of Clinical Surgery in the University of Edinburgh, will take the place at Harvard University of Professor Harvey Cushing, and has been appointed pro tempore a surgeon to the Peter Bent Brigham Hospital, where Professor Cushing has a charge of 170 beds. Sir Harold Stiles will be in charge for the last fortnight of the term and will have the fullest opportunity of studying the surgical methods practised at the celebrated Harvard School, as well as of demonstrating Edinburgh methods to the American students. He intends to be back in time to attend the meeting of the Association of Surgeons of Great Britain and Ireland during the first week of May; an arrangement of this kind, therefore, does not involve an undue expenditure of time. The development of these temporary inter-university relations must tend to broaden professional study and conduce to increased efficiency in teaching methods, as well as giving a busman's holiday to the professors granted leave of absence from their own home duties.

#### CHURCH OF SCOTLAND DEACONESS HOSPITAL.

At the annual meeting of contributors to the Deaconess Hospital, Edinburgh, the Right Rev. the Moderator of the Church of Scotland presided, and the annual report was submitted by the Hon. Lord Sands. It showed that 751 in-patients and 4,492 out-patients had been treated by the hospital in the past year, and the chairman described the hospital as, for its size, one of the most valuable institutions in the country. It had recently been recognized by the General Nursing Council for Scotland as one of the hospitals at which training qualifies for the nursing certificate. Although the training was mainly reserved for those intending to become missionary nurses at home or abroad the applications had been very numerous. The finances of the hospital had been satisfactory, the year's work showing a net credit balance of £36 as compared with a debit balance of £64 at the end of the previous year. The report was adopted on the motion of Professor G. Lovell Gulland, C.M.G., M.D.

This hospital, it may be noted, affords an interesting example of the smooth working of a contributory scheme. During the twenty nine years of its existence an increasing number of the beds have been in some instances permanently endowed and in a larger number of cases are voluntarily supported from year to year by various church congregations and other organizations such as guilds and societies within the Church of Scotland. Over 60 per cent. of the beds are thus supported with the implied condition that patients recommended by a supporting body will be given priority of admission over those on the ordinary waiting list, subject to acceptance as suitable cases by the medical or surgical staff of the hospital. The actual cost of maintenance per bed per annum is over £108, but the Board accepts £90 per annum for the support of a special bed for the above-mentioned purpose, or £45 for support of a cot in the children's ward. Private donors who have benefited from the hospital, or guilds with a personal interest, are encouraged to present £10, representing the average cost for the maintenance of one patient admitted. The scheme, which works smoothly and satisfactorily as a combination of charity and sound business principle in hospital administration, may interest those who are concerned in the changing hospital conditions of the present day.

#### LETHARGIC ENCEPHALITIS.

The medical officer of health for Glasgow has reported that since March 14th, when 39 cases of lethargic encephalitis had been notified, 18 more cases have occurred. No further deaths, however, had taken place, the number remaining at 8. During March there had been a decrease in the severity of the disease, such cases as were reported being of a mild character. The experience in Edinburgh has been similar, a decrease having appeared in the number of new cases, the mortality, and the severity in the type of case.

#### EDINBURGH ROYAL MATERNITY HOSPITAL.

During the year 1922 the numbers treated by the hospital were as follows: in hospital, 1,672; at their own homes

1,252; in the ante-natal department there were 1,297 new cases, with 3,480 revisits. Dr. William Fordyce succeeds Dr. Haig Ferguson as physician in charge for the quarter commencing April 1st, 1923, and Dr. James Young acts as assistant physician.

## Ireland.

### RECEPTION BY THE PRESIDENT OF THE ULSTER MEDICAL SOCIETY.

THE President of the Ulster Medical Society (Mr. R. J. Johnstone, F.R.C.S.Eng., M.P.) and Mrs. Johnstone gave a reception to the Fellows and Members and friends on the evening of March 22nd in the Medical Institute, Belfast. There was some delightful music, lightning sketches of some of the medical teachers in the school by Mr. Sheran, and at 10 p.m. refreshments and a dance, for which special curfew permits had been arranged. An interesting incident was a presentation to Dr. W. W. D. Thomson on his return to work after his long and very trying illness. The President, in making the presentation, said that when it was known that Dr. Thomson was returning after his long illness of two and a half years he and the secretary were inundated with requests to do something to show the profession's sympathy with one who was so popular and had reached so high a standing in the scientific ranks of medicine. No one was asked and no sum mentioned, and yet the result exceeded all expectations; he had the greatest pleasure in handing Dr. Thomson a beautiful piece of silver plate, on which were engraved the names of the 169 subscribers, and also in handing to Mrs. Thomson a diamond ring, tokens of the profession's sympathy during the long illness and a welcome on their return. A total of nearly £750 had been subscribed.

The profession is deeply indebted to the President and Mrs. Johnstone for their hospitality, and to the honorary secretary (Dr. Marshall) for the great trouble he took to make the meeting and presentation such a success.

### ROYAL VICTORIA HOSPITAL, BELFAST.

The Lord Mayor of Belfast took the chair at the annual meeting of the hospital on March 23rd in the King Edward Memorial Hall. Professor Lindsay, F.R.C.P., chairman of the board of management, in seconding the adoption of the report and statement of accounts, said that when the hospital was built in 1903 the population of Belfast was 355,000. It was now supposed to be close on half a million. Belfast was under-hospitalled; the waiting lists were increasing, and many patients were kept from treatment, and unnecessary suffering and economic loss entailed. Plans of extension had now been adopted, including three new wards, enlargement of the out-patient department, a new nursing block, and some minor details; these extensions would leave room for much needed accommodation for x rays, massage, and some special departments; the estimated cost was £64,000, exclusive of equipment. A building committee had been appointed and operations would be commenced at once, and so help to meet the unemployment.

Mr. A. B. Mitchell, F.R.C.S., in moving the adoption of the medical staff report, said that the figures, which were a "record," gave but little idea of the actual work done day by day; the medical staff had formed a high standard, and they were determined to keep it up; and he could bear testimony to the enthusiasm and energy with which the work was done. He threw out a word of caution as regards the public estimation of the x rays, which was not as simple as was often supposed; it was a highly specialized department, and required much careful and scientific study. The staff recognized with gratitude the liberality and readiness of the board of management to meet all requirements.

Dr. Calwell, in seconding, drew attention to the new department of metabolism, and said that, although started only a few months, it was already making itself felt, and was proving of great help in diagnosis and treatment. If it increased at a similar rate it would soon require laboratories, wards, and a kitchen for itself. He drew attention also to the necessity of a psychiatric clinic, which would cost nothing and would deal with those cases of incipient insanity, border-line cases, backward children, and the neuroses. Such out-patient departments, sometimes involving an arrangement with a mental hospital, were found in the Middlesex Hospital, at Cardiff, Birmingham, and elsewhere; the Maudsley Hospital was their type. Professor R. J. Johnstone, in moving

the re-election of the honorary secretary (Mr. B. M. Young) and of the honorary treasurer (Mr. Berrington), paid them a well deserved compliment for their interest in the hospital and their readiness on all occasions to help the medical staff.

### FREE STATE ARMY MEDICAL SERVICE.

The remuneration of medical officers in the army of the Irish Free State has been announced as follows:

	£	s.	d.
Lieutenant ... ..	1	0	0 a day.
Captain... ..	1	10	0 "
Commandant ... ..	2	2	0 "
Colonel ... ..	1,000	0	0 a year.
Colonel (while holding the rank of Deputy Director of Medical Services)... ..	1,250	0	0 "
Major-General Director of Medical Services ... ..	1,500	0	0 "

These salaries do not include allowances, which have not been yet fixed. At present medical officers are only engaged for one year. It is understood that when the end of the present civil war is reached the necessity for the present comparatively large service will cease, and officers will be appointed on a permanent basis at the remuneration already stated with allowances fixed on a peace basis.

Major-General M. R. J. Hayes, F.R.C.S.I., Director-General of the Free State Army Medical Service, has retired; he had occupied the position for eight months, having accepted the office temporarily to organize the service. His retirement, however, is very much regretted by the Irish profession generally, but more especially by the officers of all ranks in the Irish Free State Army Medical Service. The position which General Hayes was called upon to fill was a very difficult one, as he had to lay the foundations of his organization in the midst of a very violent civil war. It is stated that his successor will be Colonel F. J. Morrin, M.B., who has been in charge of the Corragh district for the past year. General Hayes and Colonel Morrin both served in France during the European war.

## India.

### THE RETRENCHMENT COMMITTEE.

LORD INCHEAPE and the other members of the Retrenchment Committee formally presented their report to the Viceroy on March 2nd, but copies are not yet generally available. The recommendations of the Committee are unanimous; the net reductions recommended amount to 19½ crores (£12,800,000). Of the total reduction more than 10½ crores is to be effected in military expenditure. The total reduction on expenditure on medical services and public health is put at nearly 1½ lakhs (about £9,000). The abolition of the separate post of Public Health Commissioner is recommended, and it is also advised that the directorship of medical research should be abolished, the duties being taken over by the director of the Kasauli Institute. It is recommended that the payment of research officers from central revenue should cease and that the grant-in-aid to the Research Fund Association should be discontinued. The association, it is stated, has accumulated 33 lakhs, derived from the Government contribution and earmarked for a new central institute. The interest on this, it is advised, should be used for the maintenance of medical research, which seems to imply that the proposal to erect a central institute at Delhi is to be dropped. The Financial Secretary has stated that the Government hopes to give practical effect to the recommendations of the Committee at an early date. In some preliminary comments on the report the *Pioneer* mentions that the inclusion of medical research undertaken in the interests of public health among the directions in which retrenchment can be effected on any large scale can only be regarded as false economy in the long run; any such suggestion should, it considers, be closely scrutinized. At the same time the need for economy is admitted, since for five successive years the budget has shown a deficit, and the reception of the report in India has been not unfavourable. It is estimated that the deficit for the year 1923-24 will be nearly 6 crores, although some of the reductions recommended by the Inchcape Committee have been embodied in the budget.

### RETRENCHMENT IN BENGAL.

The Bengal Retrenchment Committee has issued a report which makes some sweeping recommendations in regard to the public health service. The abolition of the school hygiene branch of the public health service is recommended, the

Committee considering that a special staff for school hygiene and the medical inspection of school children is unnecessary. A permanent assistant director for investigation into the progress of kala-azar is also believed unnecessary, a recommendation which apparently means that kala-azar field work in Bengal should be shut down. It is recommended that district hospitals and dispensaries should cease ultimately to be a direct charge on provincial revenues; the opinion is expressed that there is no reason why the Government should pay any part of the salaries of district health officers—which means, it may be assumed, the dismissal of the few existing health officers. The importance of increasing, and not diminishing, the work of the public health department in Bengal is, on the other hand, emphasized in an article in the *Statesman* (Calcutta) of February 15th. It is pointed out that what is needed in India is a modern health policy and better co-ordination of the responsible health authorities. The Director of Public Health of Bengal has repeatedly pointed out the need of improved sanitary administration in the province. Antimalarial work has been seriously hampered owing to insufficient staff, and much work remains to be done also to combat cholera, tuberculosis, beri-beri, kala-azar, leprosy, and other diseases. There is need also, it is stated, for extending propaganda work in public health throughout the province. Attention to industrial hygiene is urgently required; it has been shown that there are 680 registered factories in Bengal employing over 524,000 workers, which does not include hundreds of thousands of workers in tea-gardens, brick-fields, and other industries, nor in the vast number of minor occupations—in Calcutta alone, for example, there are over 500 printing establishments. There is, however, no staff available for the purpose of collecting information regarding industrial hygiene, as a preparation for taking the measures necessary to improve the health of the workers and the conditions under which they labour.

#### AMERICAN MEDICAL DIPLOMAS IN INDIA.

The Government of Bengal has issued a warning to Indian students against taking courses at a private institution to be established in Calcutta called "The International Medical College." This institution purports, it is stated, to train students for the M.B. and M.D. degrees of the Lincoln Jefferson University of Illinois, U.S.A.; the Bengal Government has pointed out that this university is not recognized by the General Medical Council of the United Kingdom, and that its degrees and diplomas cannot, therefore, be accepted by the Government as satisfactory qualifications for the practice of Western medical science.

## Correspondence.

### A HOSPITAL "MAINTENANCE" SYSTEM.

SIR,—I have to thank you for the friendly notice given in your issue of March 31st to my proposed "maintenance" system in connexion with the finance of our voluntary hospitals, and, with your permission, I will reply to certain points raised. They are three in number, and I will deal with them seriatim.

The first is the inquiry as to what is meant by the term "necessitous poor." The answer will not be found in any dictionary, for the expression, at any rate in Scotland, has a different meaning according as it is used by the Education, the Health, and the Poor Law authorities. It is, however, that of the latter that is implied in my pamphlet, for it was to aid that class that our voluntary hospitals were originally established, and my reply is that the expression means "persons who are eligible for hospital treatment in terms of the Poor Law." In other words, the "necessitous poor" are, as our Glasgow Royal Infirmary charter aptly puts it, those "labouring under poverty and disease." From personal knowledge and experience I am satisfied that in the present day 99 per cent. of the patients in our voluntary hospitals would not satisfy this Poor Law test, which would entitle them to free hospital treatment. That is why I state in the pamphlet that our voluntary hospitals are no longer carrying out the role for which they were originally established in the eighteenth century, the period when the first ones came into existence.

The second point in your article calling for notice is that it is difficult to make a sharp distinction between the two

headings of expenditure for maintenance of hospital and expenditure incurred for maintenance of patients. I fail to see how any difficulty can arise, seeing that the term "maintenance of patients" is distinctly limited to the cost of the food consumed by them and of the drugs, lotions, and surgical dressings used by them. The cost of the feeding of the hospital staffs is borne by the hospital and comes under its maintenance, so that there need be no confusion on this item. It is true that in the pamphlet the suggestion is made that the cost of the renewals of the ward feeding vessels and of the surgical dressing equipment might be considered as belonging to the maintenance charges against the patients, but it is such a small item that it may be omitted from them and be placed under the hospital maintenance expenses, and thus avoid any confusion. If this is done there is a clear and sharp distinction between hospital and patients' maintenance, and it is fully detailed in the pamphlet.

The third and last point alluded to in the article is the bearing that this proposed "maintenance" system has upon the present hospital policy of the British Medical Association. In my opinion it is outside it altogether, and in no way affects it. Reference to the resolutions and memorandum of the Association will show that the suggested "staff fund" will only materialize when the contributions from patients, or from any other sources on their behalf, are made to "the hospital maintenance fees." Under my proposed "maintenance" scheme nothing is paid to the upkeep or expenses of the hospital maintenance. It is a payment made to defray the expense of the food consumed by the patients and of the drugs, lotions, and surgical dressings used by them. I cannot contemplate the Association collectively advocating a claim for any share of such a payment, nor, I am sure, would members of the Association individually approve of such a step.—I am, etc.,

Glasgow, April 2nd.

GEORGE THOS. BEATSON, M.D.

### HOSPITAL POLICY.

SIR,—I have already agreed with the essentials of Dr. Fothergill's arguments (March 24th, p. 538), and support the Brighton resolution; but I remain unconvinced of error by his latest contribution and am not enamoured of his scheme for reform. Agricultural labourers furnish a large proportion of our hospital occupants and still form about one-fifteenth of the working population. They are quite unable to subscribe, in addition to their compulsory insurance, another 3d. a week against the comparatively remote contingency of in-patient hospital need. Many other workers receive small or irregular wage, and are equally incapable, while something like 10 per cent. are unemployed.

I cannot, therefore, accept Dr. Fothergill's estimate. He is evidently a convert to the so-called "Sussex," in reality Brighton and Hove, "Provident Scheme." I have studied it with care, and discussed it fully with Dr. Gordon in eighteen months ago, but was unable to recommend it to our hospital board. I am still of the same mind. Although this scheme has now been in operation for over two years, the financial position of the Royal Sussex County Hospital is quite deplorable, whereas of the eight hospitals in West Sussex where no such scheme is in operation only one qualified under the terms set out by the Hospitals Commission to obtain a grant on account of deficit. Again, out of a population in Brighton and Hove of 173,000, only 4,790 have even yet joined the scheme, and of these it is probable that a large number in other places would subscribe as much without expecting benefit, for their ordinary subscription list is particularly low, furnishing but 8 per cent. of their income, while ours yields 14.5 per cent., and 14 per cent. is the average for such hospitals. Again, although "from every side of the county has come tidings that 3d. a week was too much, the men simply could not pay it," and although even on a 3d. basis the scheme barely pays its way, despite the fact that no one can claim benefit who has not subscribed for twelve months, yet we find that the plea put forward that it is "not in any sense a charity" will not bear investigation, since nothing is allowed for the immense capital outlay on land, building, furnishing, and equipment of a large hospital. Only actual running expenses are catered for even in affiliated hospitals, and but £1 a week in others; yet these subscribers every one of whom is, if admitted, receiving charity in various degree, are taught to imagine that they are paying their full cost, remunerating the staff, and benefiting the institution in addition.

I believe that the great majority of hospital staffs is

Great Britain will decline to allow themselves to be roped into what is simply a glorified contract practice, having the drawbacks that there is neither free choice of doctor (for the doctors are limited to the staff) nor of patient (for the doctors must attend all eligible subscribers), and further that, if the scheme is really to succeed, it will require advertisement, louting, and systematic collection on a large scale, in competition with doctors perhaps equally capable not on the staff, and with hospitals outside the scheme. Moreover, I doubt extremely if the working and lower middle class will ever, except under such compulsion as can be exercised in large works or powerful unions, insure at adequate cost in large numbers against a mere possibility, especially so long as the uninsured can reap the same benefit. On the other hand, if compulsion is to be employed, it were far better done universally and equitably by municipal or Government intervention, while the refusal to admit the uninsured, however urgent his need, would be repugnant to public opinion.

Therefore I do not visualize that Utopia predicted by Dr. Fothergill, and while agreeing on other matters shall continue to believe that the only alternative to our present voluntary system, with its appeals to the charitable, is State or municipal hospitals, which most of us would avoid. For my own part, indeed, I regard that commingling of all classes towards a common beneficent object, that local patriotic pride and human interest of rich and poor together in their local hospital, which finds expression in the manner despised by Dr. Fothergill, and yields results so cogently set forth by Sir Anthony Bowlby in his evidence before the Cave Committee—that spirit I regard as not only unobjectionable, but entirely admirable, and to be commended as one of the best bulwarks left to us against those perilous forces tending towards class disruption and revolution which menace our national peace. Let us tread warily lest we lightly imperil a precious heritage, whether in search of some elusive Utopia or in mere pursuit of gain.—I am, etc.,

Chichester, March 25th.

G. C. GARRATT.

#### TREATMENT OF EARLY MENTAL CASES.

SIR.—Two letters on the subject which appeared in the JOURNAL for March 24th induce me to ask you to insert the following remarks. Both your correspondents mention the Maudsley Hospital in relation to the early treatment of mental cases. It is not perfectly clear from Dr. Goodall's letter whether he has safeguarded himself from being taken to the "Maudsley" or any similar institution in the deplorable event of his ever needing mental treatment. For the rest Dr. Goodall's letter is worthy of all acceptance. But Dr. White's letter clearly disapproves of such institutions as the Maudsley Hospital for the purpose of early treatment, and condemns all places of care of early mental cases where the patient may run any "risk" of being detained.

It is not questionable that there are many instances in which persons have shown the first signs of mental aberration and have very soon afterwards proved themselves to be in need of constant care and watching. For such cases, be they transitory or not, the attractive sanatoriums indicated, as Dr. White says, by "common sense" and apparently not subject to any approved authority, would be certainly unfitted.

Of course it is a well known fact that "mental" patients of all sorts and degrees dread the thought of being sent to a mental institution by whatever name it may be called. Equally, I deem, it is known that the near prospect of being thus treated will often contribute, or indeed lead directly to their sudden or more or less gradual recovery. Such cases include so-called "psychoses," "neuroses," and the conveniently styled category of *psychoneuroses*. More than twenty-five years ago, while in practice, I had several such cases, all apparently and rapidly cured for an indefinite time, and a few, which I was able to follow out for some years, where no recurrence of untoward symptoms took place. One of these was a case of an intensely introspective young woman with a voluminous knowledge of psychological and medical literature. After a long interview with her I informed her mother, in answer to a question whether the girl was incurable, that there was every prospect of recovery if she would let her come into a nursing home for about a week. I was told that she could not agree to this, partly because the girl would refuse to go, and partly on the score of expense. I then advised the mother to take her to consult a friend of mine who was then superintendent of an asylum, but not to inform her daughter further than that I desired to know my friend's opinion of her case. After I had communicated with him, the patient

was taken by her mother, but on arriving at the entrance the girl asked what the building was, and, though the mother told her the exact truth, she steadfastly declined to go further, walked away more actively than she had moved for many months, and very soon lost all her "psychoneurotic" symptoms. The symptoms were such as would, I think, have precluded any mental expert from sending the patient to any attractive sanatorium uncontrolled by outside authority, and necessarily unprepared to cope properly with sudden emergencies. I mention this case as it illustrates another aspect of the utility of mental hospitals, including, specially, of course, the Maudsley, in the possible treatment of early mental cases, and even of several who may never enter them. It cannot be doubted that relatives will be far more ready to take their patients to institutions like the Maudsley than to ordinary asylums, whether or no they may be admitted within.—I am, etc.,

London, W., March 25th.

H. BRYAN DONKIN.

#### SUGAR VERSUS ALCOHOL.

SIR.—I have read with interest your leading article on sugar versus alcohol (March 24th, p. 523) with respect to the reduction in their taxation. I trust, however, that the tax on sugar will not be reduced. Excessive consumption of sugar is now very common in England, and its influence in predisposing to diabetes mellitus is deserving of greater consideration. Excess of starchy food, or a diet consisting chiefly of starchy carbohydrates, probably does not increase the risk of diabetes. But, though diabetes often occurs in those who have not taken sugar in large quantities, it is probable that the excessive consumption of sugar greatly increases the risk of the disease. (I have given reasons for these opinions in articles on "The geographical distribution of diabetes,"<sup>1</sup> on "The etiology of diabetes mellitus,"<sup>2</sup> and on "The prevention of diabetes mellitus.")<sup>3</sup> Joslin has drawn attention to the marked increase of diabetes in the United States between 1900 and 1918, and points out that the yearly average consumption of sugar by each individual had greatly increased in this period. He remarks: "It is possible that the recent increase in the quantity of sugar consumed *per capita* in the United States has increased our number of diabetics."

Sugar is a luxury and not a necessity in food. If any articles of food have to be taxed there is no hardship in taxing sugar. So much sugar is now used in many articles of food, supplied in restaurants and hotels, that they are very distasteful to those who are not specially fond of sweet food. If any reduction of taxation is now possible in England, I think many readers will consider that a reduction of some other form of taxation (the income tax, for example) would be desirable before a reduction in the tax on sugar and alcohol.—I am, etc.,

Manchester, March 24th.

R. T. WILLIAMSON.

SIR.—All serious students will be grateful to you for the valuable article in the issue of March 24th. May I venture to suggest three points which emphasize some of the physiological differences in the action of these agents, which may help in the discussion the article will provoke?

1. The metabolism of sugar is under unique physiological control in the human body whereby excess within fairly wide limits is promptly and efficiently dealt with. By this means the blood sugar content is maintained at a remarkably uniform level, and the excess not needed for immediate purposes is stored as glycogen ready for future demands. Alcohol is not so controlled and it cannot be stored for future use.

2. Excessive ingestion of sugar may lead to a temporary alimentary hyperglycaemia or even glycosuria. If a second dose of sugar be given as the hyperglycaemia is declining it is followed by a much less marked reaction (Bang). Macleod, in referring to Bang's work, says: "It indicates that assimilation of sugar causes stimulation of the sugar-destroying functions of the body; the first absorbed sugar stimulates the metabolic functions." Here, again, the action of alcohol seems to be entirely different. Mellanby has demonstrated that a second dose of alcohol given eighteen and a half hours after the injection of 50 c.cm. leads to a higher concentration of alcohol in the blood, accompanied by a more profound

<sup>1</sup> Med. Chronicle, July, 1920.<sup>2</sup> British Medical Journal, 1921, 2nd, 1918.<sup>3</sup> Ibid., 1922, 2nd, 1918.<sup>4</sup> Ibid., 1922, 2nd, 1918.<sup>5</sup> Macleod in Physiological Review, American Phys. Soc., April, 1921.

intoxication. This is due, he claims, to the accumulative effect of the alcohol.<sup>1</sup>

3. With an excessive dose of glucose not only is the glyco-genic function stimulated to meet the demand for a uniform blood sugar content, but more glucose is oxidized, as evidenced by a rising respiratory quotient. Sugar has a specific dynamic action, alcohol has no such specific dynamic action; and, moreover, a high alcohol concentration in the blood not only limits its own oxidation, but also the oxidation of other sources of energy.<sup>2</sup>

These facts, coupled with many others, lie behind such a dictum as: "Throughout the body generally the presence of even a slight amount of undecomposed alcohol leads to a diminution of the chemical energy of the cells, which interferes with metabolism and may result in chronic disease. . . . The habitual consumption of alcohol in quantities which, though insufficient to produce any outward and visible signs of intoxication, are yet beyond the immediate oxidizing power of the cells, may end in playing havoc with the tissues."<sup>3</sup>—I am, etc.,

Beckenham, Kent, March 26th.

COURTENAY C. WEEKS.

#### INTRACAPSULAR EXTRACTION OF CATARACT.

SIR,—In the review of Nesfield's book on ophthalmic surgery (BRITISH MEDICAL JOURNAL for February 24th, p. 334) a statement occurs which I think should not be allowed to pass unquestioned.

It is stated that the suspensory ligament of the lens is "much tougher in Europeans than in Hindus. Hence the failure of European ophthalmic surgeons to obtain satisfactory results with the several intracapsular operations that have been evolved in India." I have extracted the lens in a number of Europeans in the capsule, and while I have met with tough suspensory ligaments in some cases, in others the operation has been as easy as it is possible to imagine. It must not be forgotten also that the suspensory ligaments of Indians are often very tough, as anyone who has extracted a few thousands of lenses knows from bitter experience. Also I think most experienced operators by the capsulotomy and allied methods have learnt by sad experience that the suspensory ligament of Europeans is often very fragile. If it were not, escape of vitreous would, I think, be less often seen in these operations even than it is. The strength of the suspensory ligament, though it may be a factor, is by no means the sole factor, nor in my opinion the chief one.

There are other reasons why European operators have not obtained more satisfactory results by Smith's operation. I mention this method as it, or some modification of it, has been very extensively practised, not only in India, but in America and elsewhere. In my opinion a very important reason why most European operators have not obtained more satisfactory results by this method is that it is a very much more difficult operation to learn than the older operations, and requires for its successful performance a much higher degree of technical skill. I speak with a large experience of both methods. To get the best results one needs to have more practice than the ordinary clinic of Europe affords to the individual operator. It is also necessary for the beginner to have a very skilful assistant. His training requires special experience which the operator does not usually possess, I have trained several and know the difficulties.

In spite of its difficulties, however, in addition to several American ophthalmic surgeons one European operator at least appears to have obtained satisfactory results with Smith's operation, for in the *American Journal of Ophthalmology* for 1920 (p. 726) E. E. Maddox reports a case in which he successfully extracted a cataract in the capsule in a patient who suffered from gout, myxoedema, and malaria, and who had lost the other eye after a cataract operation from intra-ocular haemorrhage. From private information I understand that Smith's technique was adopted.

It is certain that a cautious surgeon like Maddox would not have employed this operation in such a formidable case had his previous experience of this method not been such as to give him considerable confidence.

I am of opinion after many years of experience that much better results would be obtained by the ordinary operator if he knew how to select his cases for this operation, especially in the beginning. It is not easy I admit. If, for instance, one selects for the first operation a stout, nervous patient with

a prominent eye, escape of vitreous will be very likely to occur. If, on the other hand, one selects a thin, placid patient with a deep orbital cavity and a sunken eye, the operation will be found much easier. There are numerous other points which I cannot mention here for want of space.

Those of us who have had the great privilege of working with Colonel Smith know that he can usually recognize a difficult case, and that he would not allow an inexperienced pupil to perform the operation, no matter what his experience might have been of the older methods.

It is, however, not always possible to recognize such cases till the actual extraction of the lens commences. While Smith with his huge experience and great technical skill may be justified in extracting any lens in its capsule I believe others would do better, if not experienced, to lacerate the capsule if on trial the suspensory ligament is found to be very tough. When operating in India I always kept a sterilized cystotome ready in a separate receptacle in case it might be required, though I seldom had occasion to use it in cases which I had marked as suitable for Smith's operation.

Nesfield's operation is said by the reviewer to be simple. I do not wish to detract from its merit when I say that it is not so simple to perform as may appear from the description.

Finally, I would say that some opponents when passing judgement on intracapsular operations are apt to lose sight of the fact that loss of vitreous may occur in any form of operation for cataract and to pass lightly over the dangers resulting from lens matter left behind, the possibility of capsule being left in the wound to open the door to sepsis, and other drawbacks to the older operations.

I do not wish for a moment to underestimate the danger of loss of vitreous in any operation, but in a series of ninety-eight cases which I collected and published in 1903 I showed that escape of vitreous in intracapsular operations is apparently less serious than in capsulotomy operations, where it gets mixed up with lens matter. The average time which had elapsed after operation in these cases was three years. My subsequent experience has confirmed the opinion I expressed then, and I have had a large experience of both methods of operation, and have had special opportunities of observing the cases of other operators in India and in Europe.—I am, etc.,

A. E. J. LISTER, M.B., F.R.C.S.,  
Lieutenant-Colonel I.M.S.(ret'd.).

Amberley, Glos., March 16th.

#### PUBLIC EDUCATION IN CONTROL OF CANCER.

SIR,—The members of the Royal Society of Medicine have agreed that the public require education with regard to cancer, and that the Royal Red Cross is the body which should undertake this work. Mr. J. E. Adams (BRITISH MEDICAL JOURNAL, March 24th, p. 509) says that the Royal Society of Medicine is the headquarters of scientific intelligence in the medical profession, an observation with which one may courteously join issue. There is the Ministry of Health, surely.

The question many will ask is whether the excellent Red Cross Society is the best body to undertake this work. Surely not. To commence with, numerous local authorities have already sanctioned schemes put forward by their medical officers of health for the spreading of the light. Deptford's effort consisted in newspaper articles, the printing and distribution of literature on the subject, and a supply of pamphlets for each of the nine clinics held in connexion with ante-natal and maternity and child welfare centres.

Public health departments are clearly the best centres for the spread of information and advice as to prevention. By all means add thereto any ancillary aids to the desired end, but, mayhap, one may be pardoned for suggesting that public education regarding cancer and every other disease should be carried out with an even, insistent, and tireless reiteration to the facts by trained persons who are known to the people as the accredited and qualified representatives of the local authorities who hold the nation's hall-mark, the guinea stamp.

If the Red Cross Society takes on the work, who will supply the ammunition, the information to it, and how will the same be broadcasted? We already have Health Weeks, Baby Weeks, Rat Weeks, and, I understand, a "Pencil Week." Will a cancer week be the next to be added unto us? With the advent of infant welfare centres we have witnessed a steady fall in the infant mortality rate to its present comparatively reasonable proportions. The joint operations of the hard-working practitioner and his brother in

<sup>1</sup> Special Report Series, No. 31.

<sup>2</sup> Also BRITISH MEDICAL JOURNAL, August 5th, 1922.

<sup>3</sup> R. Hutchison, *Food and Dietetics*, 1922.

the health department has made this country the safest and the best to live in that the world has ever seen.

Could the Royal Society of Medicine do better than ask our splendid Red Cross Society to canvass for funds for those good men who are engaged in cancer and other research work? Would this not be better work than any cancer week—a rocket, a flare, and a silence?—I am, etc.,

CHARLES S. THOMSON,  
Medical Officer of Health.

London, S.E., March 26th.

SIR,—In the discussion at the Royal Society of Medicine on this subject (reported on page 509 of your issue of March 24th) no mention was made of the propaganda which has been carried out by the Central Midwives Board.

In 1908 a leaflet on "Cancer of the Womb" and subsequently a leaflet on "Cancer of the Breast" were framed at the request of the Board by its chairman, Sir Francis Champneys, and copies of these are placed in the hands of every midwife on passing the Board's examination, together with the rules. These leaflets lay stress on the earliest signs and—in leaded type—on the necessity of medical treatment without any delay. Other leaflets deal with ophthalmia neonatorum, gonorrhoea, and syphilis.

Taking into consideration the fact that these leaflets have been distributed to many thousands of midwives who are, in a sense, at the centre of action, the steps taken by the Central Midwives Board ought not to be ignored. I enclose copies of the various leaflets.—I am, etc.,

H. G. WESTLEY,

Secretary, Central Midwives Board, 1, Queen Anne's  
Gate Buildings, Westminster, S.W.1.

March 27th.

\* \* The leaflets on cancer are short and very clearly expressed. Both are endorsed, "May be distributed to the Laity as well as to Midwives."

#### IONIC MEDICATION.

SIR,—The gist of Dr. David Campbell's paper (March 10th, p. 409) is that only a small quantity of any drug could be introduced into the human body through the electric current, and that drugs so introduced enter the blood as rapidly as a hypodermic injection, have the same action, and are as rapidly eliminated. Local concentration and penetration of ions beyond the skin are also denied.

The quantity of an ion introduced electrolytically into the human body in a given time, by a given current, depends on its electrochemical equivalent and the relative speed of the ions which participate in the conduction of the current.

The electrochemical equivalent signifies the mass of matter associated with a unit charge of electricity, and was first measured by Faraday, and afterwards by Lord Rayleigh. That of iodine is 0.0013 gram per coulomb = 0.078 mg. per milliampère-minute. Therefore, in forty minutes a current of 200 milliampères would transport into the tissues 624 mg., or 9.62 grains of iodine. This is not a small quantity, and, far from being whisked off in the blood stream, it was taken up and metabolized by the cells of the body, only 146 mg. being excreted in twenty-four hours. It is this local effect that is desired in ionization.

A hypodermic injection has no local action and is carried away by the blood stream at once. But ions are active, carry a charge of electricity, are propelled by an electromotive force, and attracted by the opposite pole. They could travel with, against, or across the blood current in whatever direction the opposite pole is placed. The position of the latter determines the degree of ionic penetration and concentration. This pole is erroneously called the "indifferent" electrode in textbooks, and one is led farther astray by the instruction to place it at any convenient position. To obtain local concentration and penetration in the right direction the part under treatment should be included between the two electrodes so that ions would travel in the most accessible direction.

Results must vary according to the technique and are bound to be bad where the technique is wrong. Then the critic, like the mechanic who blames the tools, would be vehement in the condemnation of the treatment, and would even call it dangerous if the patient got burnt. Wonderful results are obtained with the right technique—the outcome of several years' experience which cannot be picked up from books.

Living tissues impregnated with saline solutions are electrolytes and conduct electricity. The electric current in living tissues consists of nothing but the double current of ions.

There is no other galvanic current to which Dr. Campbell attributes relief of pain, etc. When cocaine is ionized, is the anaesthesia due to the galvanic current? Is there no local concentration and penetration of the cocaine ions? There can be no current without the ions.

In the ionization of iodine, electrons from the generator enter the dissociated iodine atoms, and these iodine ions go through the glands of the skin and the liquids of the body. The atoms travel with their charges, and at the same rate; they are inseparable even if the ions pass from one liquid to another of different composition (Lodge). But on reaching solid conductors like muscles, nerves, ligaments, cartilage, bone, inflamed and thickened tissues, of different density and conductivity, the charges and the iodine atoms separate, but not before. The electrons get re-embodied in the atoms of the body juices, and there is an interchange of ions all along the path of the electrons to the opposite electrode, where again the ions become disembodied and are conducted along the wire. Each act of disembodiment and re-embodiment of the electrons means a modification of the ions and an adjustment of the electric equilibrium of the different tissues, particularly the diseased tissues. The body cells metabolize the iodine, the exhausted cells get recharged with electricity, germs are killed, toxins are neutralized, and healthy function is restored. With each treatment more and more iodine is unloaded along the path of the ions, and concentration and penetration are gradually increased.—I am, etc.,

London, S.W., March 19th.

CHARLES E. DE SILVA, M.D.

#### DERMATITIS AND DYED FUR.

SIR,—In my note, "Dermatitis from dyed fur," in the BRITISH MEDICAL JOURNAL (March 17th), I stated that the dye responsible for the dermatitis which has recently been so prevalent was probably a member of the paraphenylenediamine group.

Mr. Herbert Skinner, M.P.S., pharmaceutical chemist and analyst to the Royal Northern Hospital, was good enough to undertake the laborious and difficult task of identification of the dye, and has sent me a full report, of which the following is a short abstract:

The fur, cut away from the leather, yields nothing to distilled water. Dilute saline solution, alkalis, acids, and wool fat (if digested with it for a few hours), extract from the fur a coloured principle, which in its reactions and comparative tests accurately agrees with those described for the metaphenylenediamine base, which is one of those dyes stated by Dr. W. F. Castle, in his instructive letter (published in the BRITISH MEDICAL JOURNAL of March 24th, p. 535), to be in common use in dyeworks at the present time. A bichromate mordant appears to have been employed, and an ineffective technique at this stage is probably responsible for failure in fixation, proved by the ease with which the dye can be dissolved.

Mr. Skinner is satisfied that this dye is present in the samples of irritating fur submitted for investigation, and informs me that the meta-base is considered more poisonous to the skin than its better known isomer—paraphenylenediamine—which, according to Dr. Castle, is used for the deep black tones in certain types of fur. It is of considerable interest and significance to note that the dye which has been isolated is soluble in saline and wool fat, which have their analogues in the sweat and sebaceous secretions of the skin. Without such solubility it would have been a matter of great difficulty to establish a relation of cause and effect.

In justice to Dr. A. C. Roxburgh, who discusses the subject in considerable detail in your issue of March 24th, I desire to add that since my note was published I have met with several cases in which there was no oedema of the eyelids, and I should therefore elect to retract this symptom as pathognomonic of the specific reaction.

Such information concerning the place of production and issue as I have been able to obtain is so vague and conflicting that I have abandoned the attempt to determine it. This aspect of the problem is in any case one which is better left in official hands.—I am, etc.,

London, March 24th.

HENRY C. SEMON.

THE Filled Milk Bill, which previously had passed the United States House of Representatives, has been adopted by the Senate. It declares "filled milk" an adulterated article of food, injurious to public health, and states that its sale constitutes a fraud on the public. "Filled milk" is defined as any milk, cream, or skimmed milk, whether or not condensed, evaporated, concentrated, powdered, dried, or desiccated, to which has been added or with which is blended any fat or oil other than milk fat.

## Obituary.

T. J. CREAN, V.C., D.S.O.

MAJOR THOMAS JOSEPH CREAN, V.C., D.S.O., R.A.M.C. (retired), died in London on March 25th. He was the second son of the late Michael Theobald Crean, barrister, of the Irish Land Commission, and was born in Dublin in 1873. He was educated at Clongowes School, and in the medical school of the Irish College of Surgeons, taking the L.R.C.S.I. and L.R.C.P.I. in 1896. In 1902 the Royal College of Surgeons of Ireland conferred the Fellowship upon him in recognition of his distinguished services. In 1891 he received the Royal Humane Society's testimonial for saving life at sea. For three years—1894 to 1896—he was a member of the Irish International Rugby fifteen, and in 1896 went to South Africa with the British Rugby fifteen which toured in South Africa that year. He made that country his home, settling in practice at Roxberg.

When the South African war began he at once enlisted as a trooper in the Imperial Light Horse, and a few months later, in March, 1900, he received a commission as captain in that corps. In June, 1901, he resigned his combatant commission to become surgeon-captain in the same corps. He was wounded at Elandsagte, at the very beginning of the war; he was wounded again, this time dangerously, at Zygorskloof, in December, 1901, when he was awarded the Victoria Cross "for great gallantry in attending to the wounded under a heavy fire at 150 yards range, although himself wounded, only desisting when he received a second, and what was thought to be a mortal, wound." He served with the Imperial Light Horse from the beginning to end of the war (1899–1902), taking part in the operations in Natal in 1899, including the actions at Elandsagte, Rietfontein, and Lombard's Kop, and the defence of Ladysmith, the relief of Mafeking, operations in the Transvaal, including the action at Frederikstad, and operations in the Orange River Colony. In addition to the V.C. he received the Queen's medal with five clasps, and the King's medal with two clasps. At the close of 1902 he accepted a regular commission as captain in the R.A.M.C., but resigned it four years later when he joined the Special Reserve of the R.A.M.C. He then started practice in London.

When the great war began, in August, 1914, he rejoined for duty as a major, and served with the first cavalry brigade in France in 1914–15, being mentioned in dispatches in the *London Gazette* of June 22nd, 1915, and receiving the D.S.O. from the same date. In 1916 he served in France as commanding officer of the 44th Field Ambulance, and subsequently as medical officer in charge of the hospital in the royal enclosure at Ascot. In 1905 he married Victoria, daughter of Don Tomas Heredia, of Malaga, and had one son and one daughter. He received the Arnett memorial gold medal in 1902.

ELFRIDA SPENCER, B.A., M.R.C.S., L.R.C.P.,  
House-Surgeon, Victoria Hospital for Children.

THE death of Miss Elfrida Spencer, on March 17th, came as a great shock to all connected with Charing Cross Hospital and its Medical School. Miss Spencer, the only daughter of Mr. Walter G. Spencer, senior surgeon to the Westminster Hospital, and honorary librarian to the British Medical Association, was educated at the Cheltenham Ladies' College and at Bedford College for Women, London. In 1914 she passed the Final B.A. (London) examination with second class honours in classics. Her arts course concluded, her active mind then turned towards medicine. After a preliminary year at science she entered as a student at Charing Cross Hospital Medical School. From the outset of her career she was recognized as a student of considerable promise, and her sunny disposition rendered her most popular with her fellow students, while her versatility and organizing capacity made her a leader in all the social activities of the school. Miss Spencer obtained the Conjoint qualification in 1921, and was fortunate in holding, in succession, the three resident posts of house-physician, house-surgeon, and obstetric officer at Charing Cross Hospital.

We are indebted to Sir HERBERT WATERHOUSE for the following appreciation: As Miss Spencer was my house-surgeon I can testify to her skill, kindness, and zeal. She had a man's judgement and a woman's charm. To illustrate the all-roundness of her knowledge, I can recall asking her, within a few minutes, the derivation of a Greek word, the

branches of a cranial nerve, and the treatment she would adopt in a difficult surgical case, and receiving from her an intelligent answer in each instance. She proved herself a worthy daughter of one of the most learned of surgeons. Recently Miss Spencer was appointed house-surgeon at the Victoria Hospital for Children, where, for the second time, she became my house-surgeon. Only a few weeks after she had taken up her new duties a severe attack of influenza, followed by pneumonia, prematurely ended her useful life, every moment of which she had lived to the full. She leaves behind her a record of work well done and a gracious memory in the minds of her many friends.

ALFRED GEORGE SIMMINS, M.B., B.S. LOND.,  
M.R.C.S., L.R.C.P.

It is with deep regret that we record the death, within a few hours of each other, on March 23rd of Dr. A. G. Simmins and his wife. Both had recently been attacked by influenza, which in his case was followed by pneumonia and in that of his wife by heart failure.

Dr. Simmins was a student at Guy's and Westminster Hospitals and in 1914 took the diplomas of M.R.C.S. and L.R.C.P. On the outbreak of war he gave up a post under the Metropolitan Asylums Board and was gazetted temporary surgeon lieutenant R.N. on August 5th, 1914, and served throughout the war. He served on the battleship *Bellerophon*, the hospital ships *Plassy* and *Karapara*, and for a year at the R.N. Hospital, Haslar. While in the navy he took the M.B., B.S. degrees of the University of London, and also, in 1918, contributed a paper on the value in diagnosis and prognosis of the Arneith polymorphonuclear neutrophile leucocyte count to the *Journal of the R.N. Medical Service*.

After being demobilized in 1919 he acted for a time as medical registrar at the Westminster Hospital, but decided to go into general practice. He succeeded Dr. Croly at Hornsey and in a few years had built up an increasing practice there, and in 1921 he started a practice in the City, where he acted as medical examiner to the Canada Life and other insurance companies. He was also assistant medical officer in the venereal departments at the Royal Northern Hospital and the Hospital for Sick Children, Great Ormond Street. All this professional work—carried on for a considerable time without any real break or holiday—proved too much for his physical strength. He had been attending a number of patients with influenza when he himself contracted the disease, and in spite of all the devoted care and attention of his medical advisers and of his wife—herself a trained nurse—he succumbed to pneumonia. Mrs. Simmins, who had also been attacked, insisted on sharing the duties of nursing her husband. Towards the end she knew that he was dying and the shock of this, added to her own illness, was so great that she passed away in her sleep early on March 23rd, while her unconscious husband lay almost breathing his last in an adjoining room. They were laid to rest together at the New Southgate Cemetery on March 27th amid many signs of sympathy and respect.

Dr. Simmins was only 32 years of age and his wife a few years older. They leave three children—a boy of 6, a girl of 4, and a boy of 15 months; the two youngest are totally unprovided for. As will be gathered from the recital of Dr. Simmins's activities he was a man of great energy and industry, and under a quiet and unassuming demeanour he possessed considerable force of character. During the few years that he was in practice he had earned the gratitude and affection of his patients, both private and hospital. He was, moreover, a man of considerable originality, introducing several new details in the method of treating the venereal patients in his clinics. His death at such an early age is a real loss to the profession, for had he been spared he would have made a name for himself. Our sympathy is extended to the relatives and particularly to the three orphaned children.

Dr. WILLIAM THOMSON of Hull, who died on March 23rd at the early age of 39, was a native of Thornhill, Dumfriesshire, and was educated at the University of Edinburgh, where he graduated M.B. Ch.B. in 1907. In 1910 he took the F.R.C.S. (Edin.). After serving as house-surgeon at the Hull Royal Infirmary he succeeded to the practice of Dr. Parkin. During the war he did temporary work at the Hull Royal Infirmary, to which institution he was appointed surgeon in August, 1919. Dr. Thomson was a member of the East York Division of the British Medical Association. He is survived by his widow and a young son.

## Universities and Colleges.

## UNIVERSITY OF LONDON.

PROFESSOR A. V. HILL, Sc.D., F.R.S., who, as already announced, succeeds Dr. E. A. Starling in the Jodrell chair of physiology at University College, was educated at Blundell's School and Cambridge (Trinity College). He was third wrangler in 1907, and in 1909 took a first class in physiology in the second part of the Natural Science Tripos. He was University lecturer in physical chemistry from 1914 to 1919, and afterwards University lecturer in physiology. During the war he was director of the Anti-Aircraft Experimental Section of the Munitions Inventions Department and a member of the Inventions Committee. Since 1919 he has been professor of physiology of Manchester.

The chair of physiology, declared vacant; the salary is £800 a year. The chair must be received not later than May 19th, should be sent to the Academic Registrar, University of London, South Kensington, S.W.7.

The Senate will hold a reception for the sixth triennial congress of the Société Internationale de Chirurgie, which is to meet in London in July next.

The presentation for degrees will be held at the Royal Albert Hall, Kensington Gore, on Thursday, May 3rd, at 2.30 p.m. A programme of music will be provided by the Trinity College of Music.

## UNIVERSITY OF LIVERPOOL.

THE following candidates have been approved at the examinations indicated:

**FINAL M.B. AND CH.B.—Part I (Pathology):** C. P. Allen, A. Ashworth, P. D. Barling, T. Bellis, E. C. Feno, T. A. Clarke, H. A. Cole, R. Cotter, L. A. R. Evans, M. Fisher, F. F. Fuller, G. A. Garrett, M. Godwin, W. J. Griffiths, L. F. Henry, F. C. S. Hinsbeeck, S. Howard, Enid M. Hughes, Bertha H. Irvine, R. C. Jones, E. Miles, D. H. Mills, J. R. Oddy, A. Oerovi z, E. R. S. Owen, P. Strelitz, A. C. Terry-Thompson, J. J. du Toit, B. J. van de S. de Villiers. **Part II (Public Health, Forensic Medicine, Toxicology):** J. M. Brodriek, G. E. Church, R. Y. Dawbarn, J. C. D. Hammond, Clara M. V. Gleave, D. C. G. Haulon, W. F. Jones, T. S. King, W. J. Laird, C. Sharp, N. Weinberg. **D.P.H.—Doris M. Cassidy, E. R. Peirce, G. H. Potter.** **DIPLOMA IN TROPICAL MEDICINE—D. Basu, J. C. Cruickshank, Winifred I. Doherty, J. Elson, R. N. Raja, C. F. White.** Dr. J. C. Cruickshank has been recommended for the Alan H. Milne Medal.

## UNIVERSITY OF ABERDEEN.

THE spring graduate on ceremony took place in the Mitchell Hall, Marischal College, on March 28th.

Among the recipients of the honorary degree of LL.D. were Sir George Makins, G.C.M.G., C.B., consulting surgeon to St. Thomas's Hospital, and Dr. William Mackie, Fellow and past vice-president of the Edinburgh Geological Society and a medical practitioner of Elgin.

The following were the principal prize winners in the Faculty of Medicine:

Gold Medal in Anatomy: W. Marshall. Keith Clinical Surgery: A. Lyall. Shepherd Principles and Practice of Surgery: R. R. Trail. Dr. James Anderson Gold Medal and Prize in Clinical Medicine, etc.: A. Lyall. Matthews Duncan Gold Medal in Obstetrics: W. Gunn. Alexander Ogston Prize in Surgery: W. J. Ogilvie.

## CONJOINT BOARD IN ENGLAND.

THE Committee of Management of the Examining Board in England of the Royal Colleges of Physicians and Surgeons has prepared a revised synopsis of the examination in pharmacology, practical pharmacy and materia medica, drawn up by the examiners. It will come into force at the examination in October next.

The Maudsley Hospital has been added to the list of hospitals recognized for instruction in mental diseases for the diploma in medicine. It has also been decided that a candidate for this diploma who acquires himself in biological medicine, but fails to pass the discretion of the examiners be allowed to present himself for re-examination only in the subject in which he failed. The regulations have been altered also so as to allow the appointment at an institution for mental diseases to be a whole-time appointment; hitherto the appointment must have been a resident one. The Manchester Eye Hospital has been added to the list of hospitals recognized for the diploma in ophthalmological medicine and surgery, and the Calcutta School of Tropical Medicine and Hygiene for six months' course of instruction for the diploma in tropical medicine and hygiene.

The Cairo, and the Co. and Hospital, on his report recommending that the examinations and course of education should continue to be recognized by the Royal Colleges for another year. The Committee, however, proposes to make some recommendations to the Minister of Education of the Egyptian Government based on Mr. Waring's observations. The suggestions relate to the extension of the period of instruction in chemistry, physics, and biology with the subject of English, the cataloguing of the pathological museum,

the creation of additional house appointments, the provision of additional facilities for clinical instruction, and the general administration of the Government has expressed an instruction and examinations in the medical school conducted in Arabic, to be supplemented by courses given by the English professors in English. It is considered that the effect of this change will be to create two standards: (a) the course of study and examination in Arabic, and (b) a higher course of instruction and examination in English.

The Committee expressed the unanimous opinion that the Royal Colleges should definitely lay it down that the continued recognition of the school will be dependent upon instruction in all subjects of the curriculum being given in English concurrently with or supplementary to the instruction in Arabic, that the examinations to be recognized by the Royal Colleges shall be conducted in English only, and that courses of study and examinations in Arabic alone will not be given any recognition whatever.

The Committee's recommendations were approved.

## SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

**SURGERY.—K. C. Chock, M. K. El Khadem, M. A. Lawson, M. Mc. W. Lopez.** **MEDICINE.—M. A. Lawson.** **FORENSIC MEDICINE.—G. K. Butterworth, M. Hawke, C. M. John, M. A. Lawson.** **MIDWIFERY.—G. K. Butterworth, K. C. Chock, M. Hawke, H. Hirst, M. A. Lawson, H. M. White.** The diploma of the Society has been granted to Messrs. G. K. Butterworth, K. C. Chock, H. Hirst, M. A. Lawson, and H. M. White.

## The Services.

## ROYAL NAVY MEDICAL CLUB.

THE annual dinner will be held at the Trocadero Restaurant, Piccadilly Circus, W.1. on Thursday, April 19th, at 7.30 p.m. for 8 p.m. Members who wish to be present are asked to inform the Honorary Secretary, Royal Navy Medical Club, 68, Victoria Street, S.W.1, not later than seven clear days before that date.

## Medical News.

THE April course of museum demonstrations at the Royal College of Surgeons of England will commence on Friday, April 13th, at 5 p.m., when Sir Arthur Keith will demonstrate madder stained specimens illustrating the process of bone growth. On Monday, April 16th, at the same hour, Professor Shattock will give a demonstration of specimens illustrating repairs of fractures. The demonstrations, which are open to advanced students and medical practitioners, will be continued on Mondays and Fridays up till and including April 30th.

A COURSE (the sixth) of lectures and practical courses of instruction for a diploma of psychological medicine has been arranged at the Maudsley Hospital, Denmark Hill, S.E. The first part will begin on Tuesday, May 1st, at 2.30 p.m., when Sir Frederick Mott will give the first of eight lectures on the anatomy of the nervous system. Dr. Henry Devine will begin a course of eight lectures on psychology on Thursday, May 3rd, and Dr. Golla a course on the physiology of the nervous system on May 4th. The courses will be followed by practical instruction and demonstrations. The second part of the course will begin in October next. The fee for the two courses is 15 guineas, for each course separately 10 guineas. Further particulars can be obtained on application to the cashier, London County Council, County Hall, Westminster Bridge, S.E.1.

A COURSE of lectures for medical practitioners on mental deficiency, supplemented by a course of clinical instruction, will be held from May 23rd to June 2nd, under the auspices of the University of London Extension Board in co-operation with the Central Association for Mental Welfare. The course is intended more especially for those medical practitioners who are engaged as certifying officers to local authorities under the Mental Deficiency Act, 1913, as school medical officers or medical officers of institutions, or who are otherwise definitely concerned with mental defectives. The course will be based on the requirements of the syllabus for the University of London Diploma in Psychological Medicine, and the university will grant a certificate of attendance to those who attend the whole course. The fee is three guineas, and full particulars may be obtained from Miss Evelyn Fox, University Extension Department, University of London, South Kensington, S.W.7.

THE *Yorkshire Evening News* states that two gifts, each of £150,000, have been made to a fund for cancer research, for which an appeal is about to be issued. The sum to be asked for, it is stated, is two million sterling.

SIR DAVID BRUCE, K.C.B., F.R.C.P., F.R.S., has been nominated by the Council as President of the British Association at its meeting next year in Toronto.

Medical Association, 15, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853,

THE TASTE OF POTASSIUM BROMIDE.

WE have received an inquiry as to the best method of disguising the taste of potassium bromide, especially when it is given to children, but it is not easy to give a satisfactory reply. According to Martindale's *Extra Pharmacopœia*, syrup of ginger, liquid extract of glycerin, or preparations of rose or vanilla are among the best. Special flavouring preparations of glycerin to which the name of glyl and syl respectively are given are advised; a glyl flavoured with rose, or a syl flavoured with vanilla. The preparations mentioned amount to solutions of essential oils in glycerin or syrup respectively. In response to an inquiry as to whether he had anything to add to what is published in his book, Dr. W. H. Martindale mentions bitter orange and pepper-mint. Potassium bromide must not, of course, be taken in solid form, but it has been administered mixed with sodium chloride as a table salt to be taken with meals.

"J. C. G." bought in 1916 a 16-h.p. four-seater for £255, and during the last financial year a 12-h.p. four-seater for £395; the first car was then sold for £29. What its present cost would be is unknown. If it may be assumed for this purpose that the present cost of a 16-h.p. would not be less than £395, "J. C. G." is entitled to his actual out-of-pocket expenditure—that is, £395 - £29 = £366—as an expense of the "last financial year."

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 108.

NOTE.—It is against the rules of the Post Office to send letters addressed either in initials or numbers.

# An Address ON THE NEW MIDWIFERY: PREVENTIVE AND REPARATIVE OBSTETRICS.\*

BY  
THE LATE J. W. BALLANTYNE, M.D., F.R.C.P.E.,  
F.R.S. EDIN.

LECTURER ON MIDWIFERY AND GYNAECOLOGY (TO WOMEN STUDENTS)  
IN THE UNIVERSITY OF EDINBURGH; PHYSICIAN IN CHARGE  
OF THE ANTE-NATAL DEPARTMENT IN THE EDINBURGH  
ROYAL MATERNITY HOSPITAL, ETC.

THE "new midwifery" is not entirely new; hardly anything ever is quite new. It is easy to think that one is looking at a new scene whilst all the time it is an old one viewed from a new angle or in a new light. It is so to some extent with what one may call the "new midwifery"; but the new view-point has brought with it changes so momentous as to justify careful consideration and to warrant the suggestion of novelty contained in the title.

## *The Old and the New.*

The obstetrician in the past went to his midwifery case determined to prevent, so far as in him lay, difficulty and danger to mother and child; and before he said farewell to his two patients he endeavoured to repair, as far as he could, any damage done to either or both of them. He was practising preventive and reparative obstetrics. There was, however, one great point of difference in the "old" as compared with the "new" midwifery. In the "old," prevention and repair were attempted practically within the time limits of the labour itself, whereas in the "new" prevention begins away back in the early months of pregnancy, if not earlier still, and reparative measures pursue the patient without regard to any time limit and solely with respect to complete restoration of the damaged parts to their original structural and functional efficacy. In the past it has been far too common for the medical attendant to concentrate his whole attention upon the supremely critical hours in which the child is passing through the mother's pelvis in the act of birth; it has been his pride, and also his sole endeavour, to step promptly forward when labour has been evidently not proceeding normally, to "sense" with a flash what has been wrong, and brilliantly, by ingenious manual or instrumental or operative devices, to correct what has been amiss, presenting triumphantly to an impressed father and a relieved mother a more or less uninjured baby. At the end of a fortnight or three weeks he has been in the habit of saying farewell to his patients after a somewhat perfunctory inquiry into their fitness. By preventive measures founded upon ante-natal supervision and treatment the obstetrician of the present, and still more of the future, is and will be able to gain a less dramatic, a less spectacular, but an infinitely more comfortable and less exacting victory in labour; and by a careful and continued "follow-up" of his patients (mother and infant) he will be enabled to return them to the ranks, so to say, of the general population intact and fit for what the future may demand of them.

In two directions the changed outlook upon midwifery has been revealing itself; it has thrown new responsibilities upon maternity hospitals, upon medical practitioners, and upon obstetric teachers; and it has demonstrated that great possibilities of life-saving (both maternal and foetal) and of disease- and disability-preventing come with its adoption. It brings new obstetric responsibilities, but it also promises new obstetric triumphs. The promises, further, have been already, in some measure and in certain places, redeemed; successes have been realized.

## *New Obstetric Responsibilities.*

In a paper read at the Conference of the Royal Institute of Public Health at Plymouth last June (1922)\* I endeavoured to enumerate the new responsibilities laid upon maternity hospitals and their staffs by the application of the principles of preventive and reparative obstetrics. I had no difficulty in making out a somewhat formidable list both on the ante-natal

and post-natal sides; and I further showed that by reason of certain recent legislative enactments maternity hospitals were brought in to share in the burden of caring for the public health of the country in a much more definite fashion than ever before. It has always been the honourable tradition in the medical profession that responsibilities once clearly proven must be accepted; and that immediate measures be taken to fulfil all consequent obligations without argument and certainly without any preliminary bargaining as to remuneration. As soon as it is demonstrated that the maternity hospital is responsible, not only for the welfare of women in the hours of labour and in the days of the puerperium, but also in the months of pregnancy and in the time that immediately follows their departure from the institution, just so soon is it incumbent upon the hospital staff and the board of directors to provide the care required even if it entail a remodelling of the whole work and a marked expansion of the premises.

## *New Obstetric Provisions.*

To carry out the new commandment in obstetrics certain new provisions have to be made. This is primarily a matter for the maternity hospitals and the maternity nursing homes; but it has to be accepted by the general practitioner and worked into the everyday routine of private obstetric practice as well. If there is benefit in the new system of pre-natal and post-natal supervision and management it must necessarily be made available for all.

Stated first in terms of the maternity hospital, the new provisions involve the setting up of the ante-natal clinic in the hospital, with smaller and more distinctively preventive ante-natal clinics in the districts from which the patients of the institution come, and along with the staffing of these with doctors, midwives, and nurses. They involve the establishment of the pre-maternity or ante-natal ward or wards in the hospital, for the treatment of the expectant mothers who are so ill as to require such accommodation, or who, in view of special interference in labour, need to be under supervision of a daily kind. They mean the development of the venereal diseases clinic for infected expectant mothers and of the venereal diseases ward or wards for the treatment of the same women and their infants both from the obstetric and the medical standpoints. The maternity hospital must accept responsibility for these patients and for this specialized work; but, having done so it will soon discover how full of life-saving and health-restoring possibilities it is. It may yet be discovered that it will be profitable to set agoing a dental clinic also for the expectants. The provision of a small pathological laboratory for diagnosis and, generally speaking, for what is called "side-room" work is an essential part of the equipment of the new maternity hospital.

These are the provisions for the ante-natal part of the hospital, and they must be accompanied by a corresponding expansion of the obstetrical and nursing staffs. Even more pressing is the establishment of a post-natal department where the "follow-up" work can be carried on. This will involve the giving of mothercraft instruction to women, especially to primiparous women, before they leave the hospital with their babies; the setting up of a neo-natal or prematurity ward for the delicate infants; the provision of reconstructive beds for the repair of all injuries or weakenings of the generative organs in women who have been confined in the hospital—a small gynaecological department in fact; and the carrying on of post-natal clinics for mothers and babies who have left the hospital both in the hospital and also in the districts from which these patients come. These additions may seem to constitute a formidable list of new burdens to be borne by the maternity hospital of the future, but several things must be remembered; first, when the maternity is part of a general hospital many of the provisions needed will be found in other departments—for example, in the gynaecological, dental, pediatric, and medical or surgical wards; secondly, in the case of the maternity hospital which is self-contained, the same accommodation and the same staff will to some extent serve for the ante natal and the post-natal work; and thirdly, some assistance, both financial and administrative, may be looked for from the public health authorities, especially in respect of the mother and child welfare and the venereal diseases work. The last statement suggests the acceptance of the new responsibilities of the maternity hospital as a part of the general public health system of the country.

The obstetric hospital has been gradually brought from a

\* This address was delivered before the Nottingham Medico Chirurgical Society on January 3rd, 1923. In preparing it for the press the author omitted a number of passages. The proofs were revised by him shortly before his lamented death.

more or less isolated position into the general scheme of the provisioning of the country with hygienic agencies, known as the Ministry of Health and the Scottish Board of Health. The points of contact have been established through the National Insurance Act with its maternity benefit, the Notification of Births (Extension) Act, the Midwives Acts for England and Scotland, the setting up of civic and country schemes for mother and child welfare work, the launching of schemes for the prevention and treatment of the venereal diseases, and the development of a Child-Life Investigation Department in the Medical Research Council's activities. No maternity hospital at the present time can afford to stand aside from these movements. It is foolish to grumble about the State's invasion of the territory of the obstetric specialist, or to ask what it is doing *dans cette galère*. The pregnant, the parturient, and the puerperal woman and her infant have passed under the aegis of the public health authorities just as surely as the fever patient, the tuberculous patient, the insane, and the school child.

#### The General Practitioner's Part.

The general practitioner cannot, any more than the maternity hospital, afford to stand aside from new obstetric responsibilities; he, like it, must adapt himself to new conditions. Many practitioners who before the war were carrying on practices with a large proportion of obstetric cases found on their return from military to home medical work that a far-reaching change had occurred in midwifery. As a result of *inter arma* legislation he discovered, not without some feelings of dismay, a whole series of mother and child welfare agencies at work under the care of women doctors and midwives; he heard what was to him almost a new language being spoken, full of references to ante-natal work, clinics, supervision, prevention, prophylactic rectifications, maternity preventive centres, pre-natal nurses, pre-natal wards, neo-natal mortality, intra-natal deaths, and the like. At first it seemed as if in this system there was no place for him, and in some cases he simply surrendered what had always been an exacting, often an arduous, and never a very lucrative branch of family practice. If, however, he looked more closely into the matter, he modified his first opinion and saw that there was a field of usefulness for him, too, in the new midwifery; he found that expectant mothers were ready to be watched over in the time of their expectancy and did not regard as unnecessary preliminary measurements, examinations, and preventive treatment; he found that through the strict enforcement of the Midwives Acts doctors were frequently being called in for the deliveries which were in one detail or another abnormal and were acting in a sense as obstetric consultants; he found that health authorities, medical officers of health, town councils, and the like, now with an informed interest in obstetric affairs, were ready to help him in the emergencies of his midwifery practice, were prepared to set up maternity homes where he might send and himself conduct difficult cases, and were willing to aid him in every endeavour to stamp out or, better, prevent sepsis and syphilis and gonorrhoea in connexion with pregnancy and labour; he found that there were openings for him in connexion with the staffing of ante-natal clinics and dispensaries and small maternity hospitals, and he discovered that even the health visitor, when properly supervised by experienced certified midwives, might be of use in his practice by persuading patients to consult him in their pregnancies than they had ever been in the old days when ante-natal work was almost unknown. There was, perhaps, still an undervaluation of the money values of such increased ante-natal work, but there was a growing sense that the doctor, as he was now being remunerated on a higher scale and in abnormal and less and less in the puerperal woman. With all this the general practitioner was not at work for some time as a midwife with its attendant extensions did not see the necessity of this rearrangement of his practice.

In order fully to incorporate the new midwifery into general practice it would seem that certain changes must be effected.

In the first place, the new outlook must be recognized in medical education, both undergraduate and post-graduate. There have of late been signs of life among the dry bones of the established medical curriculum, and there have been whispers that the General Medical Council was considering how existing arrangements for and methods of teaching obstetrics might be improved. There has been talk of intensive courses, during which the medical student shall, say for three months, devote himself exclusively to midwifery, gynaecology, and diseases of infants and young children; it is to be hoped that if any such system be introduced the ante-natal and later post-natal aspects of midwifery will be sufficiently represented. Great good will follow if the Council will no longer ask for practical training entirely in the management of labours and puerperia, but will include attendance for a certain period on the ante-natal and post-natal work of hospitals, and possibly prescribe the number of clinics on these matters necessary for graduation. The new distribution of the emphasis which would thus be brought about would soon be reflected in the teaching, both theoretical and practical: lectures on the supervision of pregnancy and the intelligent preparation for labour would be expanded and would deal less with generalities and more with practical details, for there is great truth in the old Latin tag *generalia non pungunt*; the ordinary clinics in the hospital would be interspersed with a proportion dealing with ante-natal diagnosis and treatment and with post-natal repair and supervision; and the textbooks would not contain special chapters on ante-natal and post-natal work, but would reveal in every page the new obstetric ideal that all diseases of pregnancy be cured in pregnancy and without the artificial ending of pregnancy; that all labours be prepared for during pregnancy and conducted in accordance with discoveries then made; and that all structural repairs rendered necessary by labours be carried out before the sufferers were returned as healthy into the population. It is a rather startling fact that at present the curriculum prescribed for midwives lays more stress on ante-natal work than that for medical students. Thus the certificate of training necessary for the pupil midwife before she can appear for examination requires that she shall have "undergone a course of training in midwifery (including ante-natal instruction) extending over a certain period." Unfortunately this is not reinforced by the requirement that the candidate shall have "been instructed and supervised by a qualified midwife or nurse in the management of labour and delivery." The instruction and opportunities would have to be given in post-graduate teaching to enable the graduates of the past few years to make themselves familiar with recent advances in ante-natal and post-natal methods and aims.

In the second place, general practitioners who include midwifery in their daily work must extend the sphere of their responsibility to their obstetric patients. They must regard themselves as in charge from the earliest weeks of the gestation—from the time, in fact, when the expectant mother puts herself in their keeping. They will, further, encourage their patients to come as soon as the first monthly period has been passed; and they will find that such a request will not be disregarded so often as it would have been a decade ago, for there is a better appreciation in the public mind of the value of preventive measures in the hygiene of pregnancy and labour. At the first visit the doctor will make it his business to find out his patient's past obstetric and general health history, and, more especially if she be a primipara, he will arrange for seeing her in her own home, where he will carry out a complete examination. Possibly, if he be an up-to-date man and have a large clientele, he will set aside a certain hour or hours each week for a sort of private ante-natal clinic at his own house to which expectant mothers will be invited. At any rate he will at this first interview give his patient the same care and thoroughness of examination as he would a male patient coming to him for life insurance. Instead of merely putting her name and address and the probable date of her delivery down in his engagement book and letting her go with perhaps a vague admonition to return if she felt ill, or to send for him when her pains came on, he will make her realize not only that he has now assumed full responsibility for her well-being, but that she also is under promise to keep him informed at regular intervals of her condition (even if she detect nothing unusual and to return or send at once if she feel anything unusual. He will initiate

upon her that he is anxious to foresee and prevent dangers to herself and her unborn infant, and also to alleviate the discomforts and minor ailments of child-bearing. He will, in a word, attempt to establish at once the same degree of confidence and reliance between his patient and himself as was formerly only gained after he had attended her in a confinement and seen her safely through the puerperium. He will of course find himself described by some as a faddist, and his precautions branded as unnecessary and meddlesome; but some day he will have an honourable revenge in the rarity in his practice of the nerve-racking eclampsia and the unexpected and profoundly unsatisfactory midnight craniotomy.

\* \* \* \* \*

There will remain, however, the difficulty of adequate remuneration, a difficulty which can hardly be hoped to disappear entirely in the present generation. In time, as the general practitioner is able to offer greater security from suffering and danger in pregnancy, it will become customary to reward his or her services by fees, and so to break down the habitual attitude of mind which regards the obstetric remuneration as given for attendance in labour and the puerperium. Similarly it will be recognized that the doctor who does reparative gynaecology some weeks after the confinement deserves an adequate reward for so doing. In the meantime the general practitioner who is unable to render such aid as a gift may rightly look around for help from those who are supplying it with the assistance of Government grants. In any case in which the patient is unable to give more than the ordinary fee for attendance at labour and in the lying-in time the doctor may and ought to make use of such ante-natal clinics and mothercraft classes as may be available in the district. He may send his patient to the former for a report on her obstetric fitness, and to the latter for instruction in the provision of a layette and in the method of caring for an infant; he may do this and yet quite fairly retain his personal attendance on the woman in her labour. He may even send her to a hospital possessing ante-natal beds if she suffer from such maladies of pregnancy as hyperemesis, pre-eclamptic symptoms, chorea, etc., without severing his connexion with her. He does similar things when he makes use of the hospital or Government provisions for fevers, venereal diseases, maladies of the ear, nose, throat, eye, skin, etc., and yet remains the family medical attendant. Of course, all these new procedures cannot be looked for in a day, and they will come sooner in the city than in the rural practice. No great rearrangement of general practice such as is outlined can be carried through easily; it takes a clever engineer to insert new wheels and escapements into a complicated machine which cannot be stopped for a moment for the alterations to be made. But a beginning can be made at once; and it may be confidently expected that, as soon as the public know that child-bearing can be rendered safer and more comfortable to mother and child by the "new midwifery," the transformation will come with a rush.

\* \* \* \* \*

In such ways as have been indicated the general practitioner may come into the new midwifery: he will find it in undergraduate and post-graduate teaching, and he will be able to graft it into his daily work and make use of the various public health facilities. But in the third place he may make it an important part of his practice, specializing in it to some extent. To do this effectively he must begin at the beginning.

He must throw himself with special vigour into the midwifery part of his training, attending ante-natal clinics, even if they be not compulsory for graduation purposes; and he must familiarize himself with the public health aspects of the matter, visiting infant centres, seeing mothercraft work, learning the office work, and generally getting a grasp of the links which bind obstetrics and hygiene together. Then, after graduation, he will endeavour to gain the post of house-surgeon to a maternity hospital or home with an ante-natal department, or he may serve as resident medical officer in the ante-natal department and so gain a still more intimate and extensive knowledge of preventive midwifery. He will be wise also to study specially the venereal diseases in their relation to obstetric cases, clerking at venereal disease clinics, and studying the ways in which the presence of these maladies complicate midwifery, and the way in which the presence of a pregnancy modifies the diagnosis and treatment of the venereal diseases. He will not neglect the laboratory side of ante-natal work, and will carry out post-mortem examina-

tions on stillborn infants and those dying a few hours or days after birth. He will be wise, too, to make a special study of some little known part of the subject and publish the results of his research; he will find abundant problems to investigate. He must next try for the appointment of physician in charge of a small preventive ante-natal clinic in the town or district in which he settles; and, of course, he will be ready and willing on all occasions to go to the aid of certified midwives when they are faced by abnormal labours, pregnancies, and puerperia in their practices, or when they find themselves helpless in connexion with disease or deformity in newborn infants. In process of time he may come to be a lecturer to pupil midwives, and, later still, an examiner of them under the Central Midwives Board. In these ways, and in others which local circumstances and personal qualifications will suggest and render easy, he will find himself in possession of a practice in which midwifery, not of the old haphazard sort, but preventive and reparative, will form a large and important and a growingly remunerative part. Finally, he may devote himself entirely to obstetrics, entering the ranks of the specialists by the way of the new midwifery; he will make a better and in every sense a more fully equipped consultant by reason of the mode of approach by which he has reached his goal.

In sketching the general practitioner's part in the new midwifery I have purposely referred to him as a man. I have done so because the woman doctor is already in most cases alive to the possibilities of the situation produced by the union of obstetrics with hygiene; it fell to her during the war to carry on in this as in other branches of medical practice, and naturally enough she entered and occupied the new positions and appointments which came into being under mother and child welfare schemes and such novel developments. She does not, however, claim the new midwifery as her exclusive possession, although her sex and, more particularly, personal merit when it is conspicuously present, will undoubtedly mark her out as a suitable candidate for such posts as inspector of midwives' work and practice under the local authorities who are administering the Midwives Acts, as teacher of pupil nurses training for the diploma of the Central Midwives Board, and as physician in charge of ante-natal and post-natal clinics. There is a need for the younger men also in this sphere of medical practice, if the obstetric and gynaecological consultants of the future are to build up their reputation on the sure foundation of acquaintance with all the details of their specialty.

#### *The Gains of the New Midwifery.*

It is time now to enumerate the advantages which may be expected from the wide adoption of the new midwifery; they can be gauged from those which have already followed its partial and local employment.

There is, in the first place, the removal of anxiety and dread from the minds of expectant, parturient, and puerperal patients. It is no longer sufficient to say to such women, "Child-bearing is a natural if somewhat painful business." Their reply is, "That may be, but it has for us women, as you admit, a mortality which is not negligible, and for our infants (unborn, in birth, and newly born) a death rate which is the highest for any time in life." They may add, "Do you wonder that we who know and have seen are anxious?" To use a modern phrase, what are we doctors going to do about it?

Preventive and reparative obstetrics put the doctor alongside of his or her patient throughout the whole course of her time of anxiety. With the etymology of obstetrics (Latin, *ob*, over against, and *sto*, I stand) in his thoughts the doctor stands beside his patient during the nine months of her pregnancy as well as in the ten or twelve hours of her labour, and he does not leave her till she is restored and as fit (or fitter) for the next child-bearing as she was for the one which is just finished. Are there those who will say that such being watched over will make women apprehensive and nery? The answer from all who have any knowledge of ante-natal and post-natal work is clearly in the negative. Such intelligent and informed supervision removes nervous apprehension, worry, and strain. One can see the restoration of confidence taking place at the ante-natal clinic. The doctor listens to the woman's story, guiding her by useful questions; he does not at once say, "You'll be all right," for no sensible woman would be content with so hasty a prognosis on so limited an inquiry; but he carefully makes his examination, explaining sometimes why he is doing this or that, and then, if he find all well, he says so frankly and unreservedly,

and names a date for the patient's return to be seen again. The woman who has entered the clinic nervous, anxious, scared even, leaves it with a brisk tread and a smiling face; in the doorway she turns for a second to say brightly, "Then I'm all right; many thanks; and I'll come back in three weeks"; and the physician replies, "Yes, or at any time sooner if you feel anything, however slight, which either hurts you or is strange to you." There is another little volley of "Thank you's" from the door and the interview is over. The patient goes home happy and strengthened, and the physician goes over the facts, checks them, and tries to forecast the probable course of things, so as to be prepared at all points for whatever may emerge as time goes on.

Similarly there is removal of anxiety at the other end of the reproductive cycle. When the mother of three or four months' standing visits the post-natal clinic with her baby she and he will be carefully examined; if her organs have returned to the normal in position and in function, if suckling is going on satisfactorily, if the infant has attained the proper weight, and if there are no signs of disease in either of them, then it is a great relief to the mother to be told so. She may have questions about the future to ask, and it will be an ease to her mind to have them answered by one who has the knowledge to make the answers worth having.

There is, in the second place, a great gain from the new obstetrics in the removal of much discomfort, amounting in many cases to suffering. I doubt whether anyone who has not been in charge of an ante-natal clinic has any idea of the sum of inconvenience and malaise borne by pregnant women even in cases describable as normal; and post-natal "follow-up" work is revealing similar conditions in the months which follow many deliveries. A great deal of this suffering is removable, and much of it need not occur at all under proper supervision. Some time ago I made an analysis of 500 women attending the ante-natal clinic at the Edinburgh Royal Maternity Hospital. I found that 210, or 42 per cent., of them complained of no trouble, whilst 258, or 51 per cent., suffered from minor ailments, and 32, or 6 per cent., were gravely incommoded or seriously ill. Further inquiry among the 42 per cent. who did not complain elicited a great deal of inconvenience which was being quietly accepted as necessarily bound up with child-bearing. Of course one has to remember that this clinic served as a sort of clearing house for the dispensaries and preventive clinics in Edinburgh, and took its share also in the care of the many abnormal cases which are always being sent into hospital: doubtless the proportion of suffering will be less in other clinics and in other neighbourhoods. It can be safely said that not one of the 258 women suffering from minor ailments but was the better for her visit or visits to the clinic.

A third gain has come from the adoption of ante-natal supervision and treatment; it has as yet come only in part, and its full extent cannot yet be accurately gauged. I refer to the early and much more satisfactory treatment which can be given to the dangerous complications of pregnancy, such as the toxæmias, syphilis, abortions, and heart disease. In order to obtain this gain in its fullness the ante-natal clinic alone is of small value; an ante-natal ward, with beds and medical and nursing staffs, and if possible a small laboratory, is essential. With these things it is, in my opinion, almost impossible to set a limit to the usefulness of ante-natal prevention and cure. The same conclusion will be reached for post-natal morbid states when similar provision has been made after labour. The time has come now when it is no longer necessary to write in textbooks about so many of the serious maladies of pregnancy: "This is a very dangerous complication of pregnancy; its cause is hardly understood, and in many cases the best treatment is the induction of abortion, done early before the mother's strength is exhausted." The "best" treatment is that which sacrifices a foetal for a maternal life. The hospitalization of pregnant patients has wrought a marked change in the outlook, and the "best" treatment now is to get the case of hyperemesis, or pre-eclampsia, or pyelitis, or heart disease in pregnancy into the ante-natal beds of the hospital as quickly as possible. Having got her there the best powers of diagnosis must be applied, and the most rational treatment, founded on the diagnosis, must be administered; and these things must all be done with the new ideal in sight all the time. The new ideal is to cure the disease which complicates pregnancy, or so to ameliorate it that the pregnancy may continue and a living

child be born to a restored mother. Under the new obstetrics one writes down the so-called therapeutic induction of abortion as a failure, not as a success; no result can be called a success in which one of two persons is sacrificed for the other. It is not claimed that therapeutic foetocide can be avoided in every case, for there are still cases of pre-eclampsia which pass relentlessly on to convulsions, and of hyperemesis which defy all treatment short of termination of the gestation; but it is asserted that, with the new ideal in full view, with the disease under observation early in pregnancy, and with the appliances (diagnostic and therapeutic) of a fully equipped ante-natal department at command, the number of failures will rapidly fall.

There can be as yet no limit set to the possible therapeutic triumphs of an ante-natal department with ante-natal beds and a competent and devoted staff. When such departments have been widely provided the general practitioner will probably find that it will be for his pregnant patient's benefit and for his own ease of mind to send his serious cases of gestation complications into them, just as he sends his fever cases into hospital and his insanity cases into an asylum. Even if he decide to treat them at home under his own care, he may feel sure that with good nursing they will in many instances react to treatment, and, at any rate, he will have less anxiety with them when they fall into labour than he would have had if they had received no supervision and treatment from him in their pregnancies.

A fourth great gain in the new midwifery will be, and already is, the increase in the number of normal labours due to ante-natal work, and of normal pregnancies due to the post-natal work. Both these results will follow, and, after all, post-natal supervision and treatment is simply the ante-natal care of the succeeding pregnancy and confinement. The principle of prevention of danger and difficulty which is beginning to permeate obstetric practice is already calling forth a sort of humorous protest from the staffs of hospitals, to the effect that the ante-natal department is seriously lessening the total amount of operating at labour. Certainly the timeous application of measures decided upon after a reasoned scrutiny of all the conditions discovered during pregnancy will lead to a restriction of some varieties of operative interference and an expansion of others; craniotomy, for instance, will give place to Caesarean section on induction of labour.

The restriction of abnormal labours will make wholly for the welfare of both mother and child. Many instances might be given of its mode of production; a few must suffice. As everyone knows, pelvic presentations, especially in primiparae, are a source of danger to the infant; if they do not greatly increase the mother's risks they do, by their tendency to cause stillbirths, disappoint her wishes, depress her spirits, and retard her recovery. In all first labours and in most later ones the discovery of a breech presentation means by the new midwifery the performance of cephalic version by external manipulations, aided when necessary by the use of an anaesthetic. Similarly, transverse lies and face presentations should be turned as soon as they are detected at the ante-natal clinic. By the application of towel pads, as suggested by R. C. Buist, right and left occipito-posterior positions of the vertex may be almost certainly converted into the corresponding anterior positions, with immense relief to patient and doctor when labour comes. This is no small advantage to the general practitioner. Who would not willingly give a few minutes in pregnancy to the rectification of a posterior position rather than spend strenuous hours in labour on the delivery of a foetal head lying persistently posterior? A rectification in time saves stitching a perineum and endeavouring, often unsuccessfully, to resuscitate an asphyxiated infant. Then, again, the detection of a pelvic contraction in pregnancy, its exact measurement, and the periodical estimation of the relation of the size of the foetal head to it, will enable the obstetrician to choose in good time and to prepare for the best method of delivery at or before the full term. In one case it may be safe to leave the birth to the natural efforts aided by moulding of the foetal head; in another induction a month before term will be best; and in yet another the Caesarean section will be preferred. In any case the labour will be approached after a full and reasoned consideration of all the factors involved. We shall in the future hear less of the case in which the natural efforts were found after

These fistulae are found in front of the sterno-cleido-mastoid muscle, from the sterno-clavicular articulation to the external auditory meatus. These are the first and fourth clefts, the second and third being found between these points. They extend towards the pharynx or oesophagus. The opening may be internal, external, or both. I have never met with a complete fistula. Bland-Sutton says the length of these fistulae varies from 2 to 5 cm., and are lined with ciliated epithelium, or by skin containing sebaceous glands. A case

LECTURE V.—POSTURAL MODIFICATIONS OF THE  
PELVIS, PERINEUM, AND GROIN.

NATURE in her evolutionary creations has often, like modern statesmen, to effect a compromise between contending interests. I may cite the human pelvis as an instance to illustrate my meaning. The pelvis has a locomotory interest: it is an extremely complex lever by which the muscles of the hip and buttock balance the weight of the trunk on one or on both lower limbs. Then it has a visceral interest; it has not only to contain certain organs, but must also give suitable attachment to the musculature which supports the contents of the abdomen. It has a spinal interest in that it affords the chief base for the musculature of the vertebral column. It has an obstetrical interest, having to be so framed in women as to give a safe passage to the child at birth. It has to give attachments to the external genital organs and to the terminal parts of the rectum and urethra. Even the most hypercritical of anatomists and surgeons agree that Nature has combined these contending functional interests in the pelvis of man with the utmost ingenuity. No one has been able to suggest an improvement on her design, and yet the fact remains that in modern civilized communities pelvic defects, among which I would classify hernia and prolapse, are very common.

*Are Hernia and Prolapse to be Reckoned as Postural  
Defects?*

Are we to say, then, that Europeans and peoples of European origin are more liable to hernia and to uterine prolapse than more primitive peoples, such as the aborigines of Australia, because the European body is less perfectly adapted to the upright posture? I think not; the Australian aborigine spends his days amidst conditions very similar to those for which early man was evolved, while our conditions of living and working are of recent development, and very different from the aboriginal kind. We shall be wise to search in these modern conditions of life for the factors which contribute to our liability to hernia rather than to lay the whole blame on postural imperfections of our bodies. Two of these modern factors solicit the attention of medical men. The first of these is the states of high pressure which arise within the abdominal cavity of modern labourers during violent effort, as in lifting heavy weights, or in the physically weak during fits of coughing or of straining at stool. On standing up the pressure on the floor of the pelvis, taken from within the passive rectum and registered on a mercury manometer, will be found to vary from 15 to 25 mm. so long as we stand still, but the moment we attempt any arm movement, particularly if we bend down and seek to lift a heavy weight, the intra-pelvic pressure, as registered on the manometer, instantly rises to the neighbourhood of 80 to 100 mm. If the effort is made suddenly the initial rise is much greater—reaching as much as 150 mm. In all such movements the visceral contents of the abdomen are compressed within the envelope of the postural musculature and seek out the weakest points in the containing walls; they act as water-hammers. No one will deny that modern civilization has increased the abdominal strain for labouring men and women.

*Probable Effects of Errors in Diet.*

Then there is another modern factor at work, to which attention has been already drawn. In modern communities visceroptosis is common; we cannot explain this postural displacement of the abdominal viscera except by supposing that the reflex mechanism which controls the supporting musculature has become damaged. Such damage to the musculature of the abdominal and pelvic walls must increase the liability to pelvic prolapse and to hernia. But when we have made all allowances for these two factors—increased

intra-abdominal stresses and disordered action of the parietal musculature—the fact still remains that the modification of man's pelvis to answer the needs of plantigrade progression has weakened the pelvic walls, particularly in the regions of the groin and of the pelvic outlet.

*Defence of the Pelvic Outlet.*

The defensive structures of the outlet of the human pelvis are represented by the levator ani muscles and certain fascial and ligamentous structures. The human type of pelvic floor is not peculiar to man; it is found in all members of the orthograde group of primates—in the great anthropoids, in the gibbons or small anthropoids as well as in man. It may be called the orthograde type of pelvic floor and was evolved with the appearance of the orthograde posture. Reasons have already been given for deriving the earliest orthograde forms from a pronograde ancestry. Now in all pronograde apes, whether the tail be long or short, its root is made to serve the purpose of a perineal shutter. It was, as we shall explain, the evolution of the orthograde pelvic floor which led to the coccygealization of the tail. An external tail had disappeared from the orthograde stock long before the human form came into being.

*The Pronograde Defence.*

We can best realize the extent to which the defensive mechanism of the pelvic outlet underwent a postural transformation if we compare the pelvic structures of a pronograde ape, such as a macaque, with the same parts in the orthograde gibbon. However short the tail may be, it will be found to have its own proper muscles—muscles which rise from dorsal and ventral aspects of the sacrum and have the power to extend, flex, and move the tail from side to side. On the ventral or perineal aspect of the second, third, and fourth vertebrae of the tail are small V-shaped or chevron bones to which the guardian muscles of the pelvic outlet are attached. The guardian muscles of the outlet—which become modified to form the levator ani muscles of the orthograde pelvis—are arranged in two pairs. The median pair—the pubo-caudal muscles—arise within the whole length of the symphysis pubis, and, leaving between them a narrow chink through which escape the urethra, vagina, and rectum, run backwards to the chevron bones beneath the base of the tail. The lateral pair—the ilio-caudal muscles—arise from the brim of the pelvis and pass to the chevron bones of the tail. These muscles have fascial sheaths, so have the pelvic viscera; muscular and visceral sheaths fuse at the chink of exit. The arteries and nerves passing to the pelvic viscera are clothed with connective tissue sheathing to guard them from being strained when the floor yields. Thus the pronograde pelvic outlet is guarded by muscles to which the pelvic viscera have fascial attachments.

In the horizontal gait the pelvic outlet is the highest point of the abdominal cavity; when a human patient is placed in a similar position—on elbows and knees—the pelvic pressure becomes negative. But if the patient strains or attempts to rise the intrapelvic pressure at once mounts up. It is so in the active pronograde monkey. When preparing to jump it will be observed that the muscles which guard the outlet of the pronograde pelvis immediately depress the root of the tail and close the outlet. In defaecation the tail is raised, the median intermuscular chink is lengthened; the pubo-caudal or guardian muscles then act between two fixed points—the pubis and base of the tail.

*Shedding of the Tail.*

Conceive for a moment what would happen were a pronograde monkey to assume the orthograde posture of a gibbon. The lower end of the column, formed by the visceral contents of the abdomen, would then come to rest on the guardian muscles of the pelvic outlet—the levatores ani. The muscles would then contract and close the pelvic outlet by depressing the root of the tail; so long as the animal maintained the orthograde posture the muscles would have to keep contracted and the tail depressed and immobile. The pubo-caudal and ilio-caudal muscles have thus become postural in function when an upright position is assumed, and the depressed tail has become, except for its basal part, a useless structure. Now when a structure becomes useless it disappears; we do not know the process which Nature uses to get rid of useless structures, but we do know that the tail of the tadpole withers when the animal passes into the frog stage, and that the shedding of the tail is dependent on a

full action of the thyroid gland. We are certain, at least, that with the first stage in the evolution of the orthograde posture the external tail disappeared; the basal vertebrae became vestigial or coccygealized. The coccyx of the gibbon is more reduced than even that of man; it has reached its most atrophic form in the orang.

#### *The Orthograde Pelvic Floor.*

With the coccygealization of the tail the pubo-caudal and ilio-caudal muscles of the pronograde pelvis became spread out to form a supporting muscular hammock, but still attached to the vestige of the tail. Man's pelvic floor is an ancient heritage; it came into being with the evolution of the oldest orthograde type.\* Not only have the attachments and arrangement of the pelvic muscles been modified to suit the assumption of a new posture, but the nerve mechanisms which control these muscles must also have become modified.

#### *Evidence of the Former Existence of a Tail.*

What evidence have we that the tailless pelvic floor of man and of the orthograde apes was evolved from one which was tailed and pronograde in type? Our evidence is most complete as regards man. Children are occasionally born with true tails; in the sixth week of development the human embryo has a free projecting tail, containing nine to twelve segments; by the twelfth week the terminal three or four vertebrae have been absorbed, and a dimple on the rump marks the point at which the free tail has sunk below the surface. Most significant of all is the presence in the tail of the human embryo of vestiges of the chevron bones, which give attachment to the muscles of the pelvic outlet in pronograde monkeys. We cannot explain the vestiges of chevron bones in our bodies, nor of a caudal lobe in the liver, nor of the azygos lobe of the right lung, unless we suppose that there was a pronograde stage in man's ancestry.

#### *Evolution of the Human Perineum.*

The outlet of the human pelvis is a diamond-shaped space, made up of rectal and urethral triangles. The posterior, rectal, or ischial part of the outlet is old; the anterior, urethral, or pubic part of the space is new. In pronograde monkeys the ischial tuberosities come almost into contact; the whole outlet in them represents only the posterior part of the outlet of the human pelvis; only a rudiment of the pubic part of the space is present. In the gibbon the ischial tuberosities and rami are as in pronograde apes, but in the orang, chimpanzee, and more especially in the gorilla, the ischial tuberosities do not meet and there is the beginning of the subpubic space which becomes so marked a feature of the human pelvis, particularly the pelvis of European women. In anthropoids the perineum is placed on the dorsal surface of the body; the roomy outlet of the pelvis looks backwards; the symphysis forms the lowest part of the pelvis. The levatores ani enter into the formation of the posterior wall of the pelvis rather than form a floor for it. In the human pelvis the posterior part of the outlet has been diminished in size and strengthened in its framework (1) by a bending forwards of the apical part of the sacrum and a strengthening of the vertebrae of the coccyx; (2) by a strengthening of the great sacro-sciatic and small sacro-sciatic ligaments. These ligaments are present only in orthograde primates. But if the human pelvic outlet has been strengthened posteriorly it has been weakened anteriorly by the opening out of the subpubic arch. Also the symphyseal part of the human pelvis has been tilted upwards, in the direction of the umbilicus; it comes to occupy a higher level, taking the coccyx as a guide or mark, than is the case in man's nearest allies, the great anthropoid apes. These changes have brought the human vulval orifice towards the anterior or ventral surface of the body. They have also brought the levator muscles into a more horizontal position so that in man they form a pelvic floor designed to support the abdominal contents.

#### *Pelvic Supports Strongest in Man.*

At this point I cannot forbear giving a quotation from the writings of John Hunter.† "The contents of the human pelvis," he wrote, "adhere to the sides by a much greater extent of surface than in any other animal. The intention of this is perhaps to prevent a protrusion of these parts (the

womb, the bladder, the rectum, and bowel) from the weight of the viscera above, in the erect posture of man." Since the above passage was written, some one hundred and fifty years ago, we have learned that these pelvic adhesions are almost equally extensive in the orthograde primates. All have wide adhesions, fascial unions, and vascular supports, but in strength and toughness they reach their climax in man. These adhesive supports came with the evolution of the orthograde posture. In all pronograde forms only part of the bladder and uterus lie within the pelvis. In the human infant, as in the young of anthropoids, the pelvic viscera are situated as in pronograde apes; but in the adults of anthropoid, as of man, bladder, uterus, and ovaries have sunk within the cavity of the pelvis. A natural visceroptosis takes place at the lower end of the abdominal cavity of all orthograde primates as adolescence is reached.

#### *The Dimensions of the True Pelvis.*

We are apt to think of the human pelvis as being exceptionally capacious. The conjugate diameter of the pelvis of the gorilla is often double that of the human pelvis; in the chimpanzee the conjugate is half as much again as the human. In transverse width the true pelvis of the gorilla attains human dimensions, while in the chimpanzee it falls short. In depth the anthropoid pelvis is the greater and its outlet the more roomy. In them there is no pelvic bar to the birth of big-headed progeny. And yet, in spite of their orthograde posture, they do not seem to suffer from the forms of uterine prolapse to which women are so liable.

#### *The Weak Point of the Female Perineum.*

Why, then, are women, particularly women of European stocks, so liable to uterine prolapse? The weakest point in woman's pelvic floor is represented by the vaginal passage; the vaginal canal, like the inguinal and femoral canals, may become the site of a hernia. It is not the mere presence of the vaginal passage which makes a woman liable to prolapse; the rectal or anal passage would be equally weak, did it not possess strong muscular coats guarded by efficient sphincters. The vagina has neither strong muscular coats nor an efficient sphincter. In the anthropoids this passage is no better protected than is the human one, yet it does not become the site of prolapse. No doubt the opening up of the subpubic space and the tilting up of the pubic part of the pelvis to bring the vulva towards the ventral surface of a woman's body has weakened the vaginal and vesical areas of her pelvic floor. But the chief causes of woman's liability to prolapse have to be sought for, as is the case in all hernial formations, in the high and varying degrees of pressure generated within the abdominal cavity in consequence of the plantigrade posture. As already pointed out, when we sit or stand the column of abdominal viscera becomes the core within a compressing cylinder of postural musculature. Every movement of the arms, every cough or strain, sets going a multitude of water-hammers within the abdominal and pelvic cavities which search out the weak points in the surrounding walls. Just over the vaginal passage is the *perineal membrane*; every intra-abdominal impulse sets at the vaginal exit. At the upper end of the *cervix* of the uterus; it too responds to intra-abdominal pressures and strains, beating downwards into the passage. It is the continual repetition of small forces, more frequently than the sudden application of a great effort, which wears down the vaginal defence.

In cases of uterine prolapse, several of which I have had an opportunity of examining after death, I have found the muscles of the pelvic floor elongated but not atrophied. The ligamentous supports had become stretched; the pelvic structures had been forced outwards. Yet, I think, it will be found that prolapse would not have taken place if the musculature of the pelvic floor and the musculature of the vagina and supporting tissues of the uterus had been normal in tone and possessed the reflex reactions of health. There is a great lack of any real evidence on this point, but of this there can be no doubt—the idle and luxurious are just as liable to these infirmities as are women who have to perform heavy labour.

#### *THE EVOLUTION OF THE HUMAN GROIN.*

We now turn to the human groin to see if our knowledge of its evolution can throw any light on its two weak points—the inguinal canal and femoral ring. In all primates, in

\* For fuller details see Peter Thompson's *Myology of the Pelvic Floor*, R. H. Paramore's *Hunterian Lectures*, and also Keith's *Embryology and Morphology*, fourth edition, 1921.

consequence of an elaborate series of developmental or growth processes, parts of the abdominal cavity containing the testes are extruded and come to occupy a position in the scrotum. In pronograde monkeys the peritoneal passage, although very narrow, remains open; in orthograde primates it usually becomes closed; but even in man, in whom the process of closure is most complete, the canal remains unclosed in 30 per cent. of newly born children. In all primates, then, there is a breach in the musculature of the groin caused by the descent of the testes or of the round ligament. In all there is a second breach in the groin caused by the passage of the great blood vessels from the abdominal cavity to the thigh. The vascular aperture of the groin must vary in size; at times the vessels—particularly the vein—are greatly distended; at other times they are partially collapsed, thus giving a potential space for the escape of abdominal contents. In man the femoral vessels are of exceptional dimensions in consequence of the massive development of his thighs; hence in him the vascular apertures of his groin are large. It is not the presence of an inguinal canal or femoral ring which makes the human groin exceptionally liable to become the site of hernia, for these apertures are a common possession of the whole order of primates.

#### *The Groin of Apes.*

The human groin is one of the most distinctive features of man's anatomy; it is in a class by itself; in only one animal do we find a tendency towards the human form, and that is in the gorilla. If we did not possess some of the intermediate stages it would be difficult to believe that the human groin had been evolved from a pronograde form, such as is seen in the commoner monkeys. In monkeys the infraumbilical part of the belly has a narrow keel-like form terminating posteriorly at the sharp projecting symphysis pubis; on each side is the long narrow furrow or fold of the groin, separating the abdomen from the flat inner surface of the thigh. The two groin furrows form a V-shaped arrangement, the limbs of the V ending above at the anterior superior iliac spines, which are buried in the flanks. In the fold of the monkey's groin can be felt the particularly long anterior edge of the ilium, offering a firm line of attachment for the musculature which controls the apertures of the groin—the lower parts of the internal oblique and transversalis muscles. The groin is further strengthened by the fact that the external oblique muscle has no insertion to the iliac crest, but expends its strength on rendering tense the structures round the apertures of the groin. The whole arrangement makes up a most competent sphincteric mechanism; although the peritoneal passage to the scrotum remains open, escape of the abdominal contents is very rare. Further, these guardian muscles are under a reflex control.

#### *The Orthograde Groin.*

With the evolution of the simian orthograde posture the form and structure of the groin underwent surprisingly little change. In the gorilla we find a premonition of the changes which have transformed the human groin. The first of these is the extension of the crest of the ilium in an outward and also in a slightly forward direction. The fibres of the external oblique muscle, which rise from the lower ribs, no longer sweep to the groin but are inserted to the anterior end of the extended iliac crest; there is also the first appearance of the inguinal (Poupart's) ligament, formed out of the tendinous fibres of that part of the external oblique which is inserted to the crest. Further, in the gorilla the anterior border of the ilium, lying along the fold of the groin, has become relatively short. In man these changes have reached a climax; the crest of the ilium has become extensive and has undergone a marked bend forwards; the external oblique has gained a powerful insertion to the crest, and Poupart's ligament has become a strong and differentiated fibrous bridge between the anterior superior iliac spine and pubic spine. Lastly, the anterior border of the ilium has been reduced to a little more than a third of the primitive length seen in great anthropoids; the long iliac border which gave so secure an origin for the guardian muscles of the groin has gone. The lower parts of the internal oblique and transversalis muscles have now to seek a less advantageous origin from a new base—namely, Poupart's ligament. The folds of the human groin have been shortened and opened out, and thus assumed a wide U-shaped form. The lower abdominal region has become flattened in front.

All these changes have weakened the defensive mechanism of the human groin. To understand the meaning of these changes one has to remember that the pelvis is made up of a series of levers, which serve in balancing the body on the thigh. The climbing habits of the great anthropoids demand long and powerful pelvic levers; to suit man's plantigrade needs, to balance the body quickly and easily as he walks, short pelvic levers with short-fibred but powerful gluteal muscles become necessary; hence the transformation of his pelvis and shortening of his groin. It is not the orthograde posture which weakened the human groin but the transformation of his pelvis to suit the needs of plantigrade progression. As we have already seen, plantigrade progression is necessarily attended by high degrees of intra-abdominal tension. Modern methods of living—exactly how we do not know—can damage the reflex postural mechanism of the belly wall. Man's liability to hernia must be sought for in all these factors.

#### *The Liability to Femoral Hernia.*

At the beginning of this lecture I pointed out that the human pelvis was the sport of contending interests. In answering the needs of locomotion it has become less efficient as a part of the abdominal wall. In the liability of women to femoral hernia we see a disharmony between the sexual and containing functions of the pelvis. At puberty a growth takes place in the pelvis of women at three sites—at the symphysis pubis and at the two ilio-sacral joints. The new bone laid down at these joints leads to an increase of all diameters of the pelvis. Exactly the same kind of growth is seen in the pelves of men suffering from the later stages of acromegaly; the sexual transformation of the pelvis is the result of a growth mechanism controlled by hormones. In women, in whom the sexual growth is marked, the pubic part of the pelvis becomes elongated and the vascular compartment under Poupart's ligament widened.<sup>2</sup> Hence an increased liability to femoral hernia in women. A femoral sac is never the result of a developmental process; it is a structure which has never been seen at any stage in the development of human embryos or fetuses.

## VENOUS PULSATIONS AND VENOUS TRACINGS IN GENERAL;

WITH SPECIAL REFERENCE TO THE "V" WAVE OF THE POLYGRAPHIC TRACING.

BY

HARRINGTON SAINSBURY, M.D., F.R.C.P.,  
CONSULTING PHYSICIAN TO THE ROYAL FREE HOSPITAL AND  
THE VICTORIA PARK CHEST HOSPITAL.

In the first place it must be stated that the polygraphic tracing is a fact; it is Nature's own record. This is true, but the statement needs qualification, for an instrument intervenes between Nature and the recording surface. Nature, therefore, actuates a mechanism, and we must ask, Does the latter transmit faithfully, does it render an exact transcript? This is a primary question, and it raises an element of doubt as to the record.

Passing from the objective side of things to the subjective, we find the observer—another instrument, but one much more complex—intervening between the tracing and its real significance. The observer reads, conjectures, draws conclusions, and makes pronouncement, the judgement speaking the final word. But the judgement, Hippocrates tells us, is difficult, "*judicium difficile*" (Book I, Aphorism 1), and it is fallible we know. Again, therefore, there enters an element of doubt, this time as to the interpretation.

Proceeding now to the subject before us let us endeavour to follow, as closely as we are able, the course of the cardiovascular activities, as they repeat themselves in each cardiac cycle; then let us look at the tracings obtained by the polygraph and see in how far the two harmonize the one with the other.

We shall first note that normally the venous flow from the capillaries onwards presents a smooth current without trace of pulsation, until we come within a certain radius of the

heart. True the velocities change, increasing as we proceed centrally, but these merge into each other insensibly: the current keeps its smoothness.

Within the certain radius mentioned the blood in the veins comes into touch with the events passing through those chambers, and theoretically should be influenced by and show these events. The events are two—namely, (1) the auricular systole, (2) the ventricular systole; juxtaposed, they follow in

FIG. 1.—The diagram measures the time relations but not the magnitudes of the two systoles. The cardiac cycle, calculated upon a pulse rate of about 72, measures 8/10 sec. The figures must vary with different pulse rates. The duration of the auricular systole is about 1/10 sec. Thus the auricle is active for 1/10 sec., and rests for 7/10; the ventricle acts during 3/10 sec., rests for 5/10. The auricular and ventricular cycles, taken separately, overlap by 1/10 sec.

this order, with an interval scarcely perceptible between the two. A pause follows, then the couple reappear. The auricular systole is a small act, difficult to determine except instrumentally; not so the ventricular, and therefore we usually reckon the cardiac cycle from the onset of one ventricular contraction to the onset of the next, as for the pulse. It would, however, be more physiological to reckon

from auricular systole to auricular systole, as this would not dissociate the two systoles.

Each systole, being a muscular act, is more or less abrupt in its onset and ending. Each, while it lasts, interposes an obstacle to the venous afflux; each, when it ceases, withdraws that obstacle and the accumulated blood unloads itself, readjusting pressure differences. This done, the afflux is resumed under a uniform *vis a tergo*—namely, that obtaining in the tributary veins of the right auricle.

As to the *vis a tergo*, it will be remembered that in the great veins at the root of the neck the pressures in health are very small—namely, from 0 to -8 mm. Hg. Unfortunately we have very little precise information concerning the venous pressures which rule in pathological conditions, and therefore, in dealing with this aspect of things, shall be obliged to rely mainly on presumptive evidence.\* Before entering upon this it will be advantageous to introduce here a diagram, which is intended to show certain points bearing directly upon the subject in hand.

FIG. 2.—The figure is based upon Henle's *Handbuch der Anatomie*, second edition, p. 342, with considerable modifications, as follows: The veins are shown in thin line; the heart itself in thick line; the arterial system in dotted line; and the lymphatic system in dashed line.

of distribution corresponds to an area of no valves, for, though the internal jugulars have valves at their endings, these are rarely efficient, and the venous blood is free to flow in either direction. In case of the circular fibres of the auricle they are marked on the is during auricular contraction. I.J. = Internal jugular; Sp. = Site of sphincter fibres.

This diagram before us, let us consider the effect of the auricular systole upon the venous afflux. The circular disposition of the auricular fibres around the cavæ must tend to close them more or less, and in health the probability is that the closure is very appreciable, perhaps almost complete, otherwise the systole would be defeated in its objective, taking effect backwards into the capacious, thin-walled,

ill-filled veins as the line of less resistance, rather than forwards into the already partially filled and thick-walled ventricle. It is most probable, further, that this sphincter action is an *initial* event of the systole, for, the end in view being the raising of intra-auricular pressure, here also would be more or less frustration unless leakage backwards were checked from the outset. The part played by these sphincter fibres in auricular systole would thus be the equivalent of the action of the *a-v* valve in ventricular systole—namely, to supply a *point d'appui* for the contraction of the heart walls.

Assuming complete closure of the cavæ during auricular systole the effect would be the same as that of ligation of both vessels; no impulse would be sent back into the veins, but behind the block and proceeding backwards from it the blood would gradually accumulate. Can we see here the development of any wave (justly so named) within the veins by the smooth afflux under the low pressures of health? The period of accumulation lasts one-tenth of a second.

Assuming incomplete closure of the cavæ in health there will be more or less of actual reflux from the auricle and a wave of sorts might be registrable in the internal jugular, in spite of the comparatively small power of the auricular contraction, which would scarcely be able to generate a percussion wave. Such wave would be pre-ventricular systolic in time and in magnitude it should be quite small.

In disease, where marked congestion of the right heart and its great venous tributaries was present, there would be appreciable reflux, and it there should happen to be much hypertrophy of the right auricle (a rare occurrence) the reflux would be proportionately greater and an actual percussion wave might be present.

Whether in health or in disease, if there is reflux, it would add its volume to the accumulation by afflux, which would continue unchecked during the whole of the auricular systole. The congestion of the veins would be correspondingly accentuated, but the factor bearing the pulsation would be the reflux, not the afflux, which *ex hypothesi* contains no pulsation.

Reverting to the venous afflux, there arises an interesting question—namely, During congestion of the veins, however brought about, does the intravenous pressure begin to rise forthwith and proceed *pari passu* with the accumulation of the blood? The answer is, No; there will be no appreciable rise until the veins have reached their full capacity and their walls have begun to be distended—that is, stretched. Until stretch begins there is no resistance; until resistance begins there is no rise of pressure. But the venous system in health is never distended, in particular the great venous trunks; there is not enough blood in the body to distend arteries, capillaries, and veins. The valveless cavæ and their main branchings interpose thus a very large potential capacity between the heart and the main body of the valve-bearing veins, and until congestion has exhausted the whole of this superfluous capacity no perceptible rise in blood pressure can take place. In life the feature of the arterial system is its stretch; that of the great veins their slackness. This slackness ensures the uniform delivery of blood into the heart by preventing—or shall we say keeping down?—rise of blood pressure in the great veins during the temporary obstructions at the heart caused by the systoles of auricle and ventricle.

A complete venous block of one of the smaller or medium-sized veins may be followed by great rise of blood pressure in its branchings, but time is of the essence of this *local* manifestation; it is slow. Block at the heart itself (due to the systoles) lasts one-tenth of a second for the auricle, three-tenths of a second for the ventricle. No appreciable accumulation can take place within these short intervals.

If we put at about 4 oz. the capacity of each of the chambers of the heart, and assume that in systole the chambers empty themselves, then during each auricular systole of 1/10 sec. the amount of blood held up will be only 4.3 oz. (the cardiac cycle being 8/10 sec.)—that is, half an ounce—and during ventricular systole (3/10 sec.) it will be exactly 1½ oz. These quantities are small when compared with the size of the valveless area of the great veins, and should be easily accommodated without appreciable rise of pressure when the accumulation is by *afflux*.

If the chambers do not empty themselves the quantities of blood will be proportionately reduced.

As to the local rise of blood pressure in *reflux*, we gather that no figures are available.

Contrasting venous afflux, in its continuity (evenness) of flow, with venous reflux, in its discontinuity, we shall note that, whereas the former will tend to spread its accumulation (during arrested flow) over a large venous area, by reason of the gradual distension effected, and so will minimize rise of

\* I am indebted to Dr. Charles Bolton, C.B.E., F.R.S., for information on this point.

blood pressure; the latter by its relative suddenness will limit distension to the parts nearest the heart, thus causing much greater rise of blood pressure *in situ*. This will be most observable in disease with marked backflow.

#### Right Ventricular Systole.

At the cessation of auricular systole the state of the ventricle should show:

1. The ventricular walls slightly on the stretch as a result of the auricular thrust.
2. The tricuspid valve in position and slightly on the stretch, owing to the elastic recoil of the ventricle. The latter involves a slight backward movement of the valve, but this is probably too small a quantity to impart any appreciable impulse to the contents of the auricle, let alone to record itself in the internal jugular vein. This minimal thrust would immediately precede ventricular systole.

At the same point of time the state of the auricle would show:

3. The auricular walls in complete relaxation (including, of course, the sphincter fibres of the cavæ); the blood content everywhere in contact with the flaccid walls and in direct continuity with the blood in the great veins; the auricular walls absolutely passive and ready to be dilated by venous afflux or venous reflux (should the valve be incompetent); the blood content ready to receive and transmit any impulse impressed upon it by the ventricle.

The ventricular systole now sets in with a force and abruptness far exceeding that of the auricular systole. In a piston-like stroke the tricuspid valve is driven towards the auricle, carrying with it the blood in the funnel-shaped space between the valve segments. The stroke takes effect upon the contents of the auricle, and a wave of propulsion or percussion is started and transmitted along the fairway of the open cavæ into their main branchings. There is nothing to hinder such transmission, and the slack walls of the auricle lying passively upon their contents should favour oscillation.

Should the tricuspid valve be incompetent more or less of reflux will add itself to the wave, modifying its characters. In heart disease with overloaded right chambers the reflux may be very marked and appear in the veins at the root of the neck as a pulsation definitely ventricular systolic. No sphincter action intervenes, as in the case of the auricular systole. If, then, this latter can register itself in the internal jugular, the stronger unimpeded ventricular impulse should surely be recorded.

The time of this wave will be early ventricular systolic. As to magnitude, and as measured by the forces engaged in its production, it should greatly exceed the auricular systolic wave.

Another wave must now be considered, which is also ventricular systolic, and, according to accepted teaching, appears at the root of the neck. Its cause is referred to the left ventricle, which develops it at the origin of the aorta and propagates it thence throughout the arterial system as the pulse. Its presence in the jugular vein is explained by the close proximity of carotid and jugular, whereby the throb in the artery is communicated to the contents of the adjacent vein. This is a percussion wave pure and simple; the venous flow is in nowise affected; no question of reflux arises; no changes in the volume of the blood within the vein accompany the wave. This is the *c* wave of the venous pulse tracing.

The time of this wave is ventricular systolic, but it is not earliest systolic, for it does not begin till after the *a-v* valve has been fully closed, and not before the blood pressure within the left ventricle has been raised sufficiently to force the aortic valve. It therefore must follow upon the early ventricular systolic contraction.

There remains for discussion a wave marked "*v*" on the polygraphic tracing, which is said to arise during the ventricular systole, and is regarded as owning two factors—namely:

1. A rising intra-auricular and intravenous pressure due to afflux.
2. A sudden fall of the pressure upon the onset of ventricular diastole.

It has been described as a wave of storage or *stasis*. The name is unfortunate, for a wave is essentially a dynamic manifestation, and statics do not beget dynamics. The

\* There is no such thing as an actively expanding auricle.

teaching amounts to this, that the gradual venous congestion of arrested afflux during the ventricular systole accounts for the up-stroke of the *v* wave; the sudden onset of ventricular diastole for the down-stroke. But, if so, then the up-stroke should be as gradual as the venous accumulation and the down-stroke as sudden as its release—that is, as short as the click of the second heart sound. The form of such "wave" should be as shown in Fig. 3.

FIG. 3.—Intravenous pressure curves of arrested afflux during auricular and ventricular systoles.

But true waves, undulations, are ridge-and-trough manifestations, each one of the series showing the descending limb as the counterpart of the ascending limb; presenting, in fact, just such a curve as the *v* wave shows (see Fig. 4).\*

FIG. 4.—Phlebogram and radial tracing from a normal individual. Note in particular the form of the *v* wave.

There is evident conflict here between the tracing and the process which is held to be responsible for it. Quite apart from this argument as to the form of the wave, it is difficult to conceive how a head of pressure of only 0 to -8 mm. Hg could yield a wave of magnitude even approaching that shown.

#### Summary.

To summarize, with brief comment, the cardiac sequence of events and the polygraphic tracings.

1. *The Auricular Systole*.—The *a* wave appears to conform with this in time, but so close-set are the two systoles that more exact timing seems desirable; in magnitude the tracing seems disproportionately great, seeing the small power of the auricle and the block interposed by the sphincter action at the mouths of the cavæ.
2. *The Auricular Diastole*.—No hint of this shows on the tracing, though the ventricular diastole is credited with causing so marked a feature in the phlebogram.
3. *The Ventricular Systole*.—This is a very powerful and abrupt event; the conditions for backward transmission are very favourable, all sphincter action being withdrawn. Why is it conspicuous by its absence from the tracing?
4. *The Forcing of the Semilunar Valves*.—This event takes place in the course of the ventricular systole, at some time subsequent to the closure of the auriculo-ventricular valves. It should therefore be preceded by an early ventricular systolic wave, whereas it stands alone.
5. *The Onset of Ventricular Diastole*.—This event is supposed to correspond with the onset of the down-stroke of the *v* wave; but the want of conformity of this wave of the tracing with its theory of production has been dealt with. As shown it is exactly like waves *a* and *c* in type, yet in mode of production quite different.

In view of these apparent discrepancies I suggest a reference of the whole subject to the physiologists.

\* For permission to use this figure I am indebted to the courtesy of Dr. Frederick Price and the Oxford Medical Publications. See Dr. Price's *Textbook on Diseases of the Heart*, 1918, Fig. 53, p. 101.  
† Do we know what is the exact point of time when the semi-lunar valves are forced?

THE congress of French-speaking gynaecologists and obstetricians, which is held every two years, will take place at Geneva on August 9th, when the following subjects will be discussed: (1) The indications and technique in operations for retro-deviations of the uterus apart from pregnancy; introduced by MM. Henneberg and Pronst; (2) treatment of pregnancy complicated by tuberculosis, introduced by MM. Voron and Weymeersch; (3) methods of anaesthesia in gynaecological operations, introduced by MM. Kappeler and Schickele.

## A CASE OF CHRONIC INTUSSUSCEPTION.

BY

G. A. EWART, F.R.C.S.,

ASSISTANT SURGEON, ST. GEORGE'S HOSPITAL; SURGEON, HOSPITAL OF  
BS. JOHN AND ELIZABETH.

THE case recorded below is of interest not only on account of the long duration of the intussusception, but also because of the condition found at the first (palliative) operation, and the discovery at the second operation of a tumour which proved on examination to be a carcinoma.

A man, aged 68, had for a year been greatly troubled by constipation. Three days prior to admission to hospital he had taken a large dose of purgative, and the bowels had acted once; there had been no action since, and pain in the rectum and copious discharge of blood-stained mucus. Vomiting had not occurred.

The abdomen was considerably distended, and peristalsis was obvious. On examining the rectum the anal sphincters were found to be very lax, and a tense smooth mass was discovered reaching to within half an inch of the external orifice.

The patient on overhearing a remark that "there was something to be felt" volunteered the fact that he himself had made that discovery over a year previously, and had noticed something inside the rectum constantly, this discovery coinciding in point of time with the onset of his constipation.

Immediate operation was advised; this the patient refused, but changed his mind on the following day, when the symptoms of intestinal obstruction had become more distressing.

The patient was anesthetized and placed in the lithotomy position, to facilitate a more thorough examination. On passing a speculum it was found that the rectal mass was trunk-shaped, and digital examination failed to reach any attachment to the rectal wall. The only possible diagnosis seemed to be chronic intussusception causing obstruction, through engorgement brought about by purgation.

The patient was placed flat on the operating table and the abdomen opened by retracting the left lower rectus outwards. An intussusception of the sigmoid into the rectum was found, the ensheathing joining the entering layer, at a point about one inch above the recto-sigmoid junction. All the intestines were greatly distended, the large intestine, as far back as the caecum, being a solid mass of faecal material; this seemed to bear out the patient's statement of the duration of the trouble. All attempts to reduce the intussusception proved of no avail, even though one hand was placed in the rectum to manipulate its apex. In these circumstances some palliative measure had to be decided on, the choice lying between caecostomy and colostomy. Eventually colostomy was performed through the outer left rectus with the idea that it would give more efficient drainage to the overloaded intestine, and in the event of the patient refusing further operative measures allow him to get about. The colostomy was opened at the end of twenty-four hours by simply cutting across one of the longitudinal bands. The patient got on well, but the discharge of blood-stained mucus from the rectum continued.

Six weeks after operation rectal examination showed that the intussusception had considerably decreased in bulk, but still reached to within three-quarters of an inch of the anus. It was decided to open the abdomen again to see if the intussusception could be dealt with in any way. The patient was put in the Trendelenburg position, and the abdomen opened by displacing the left rectus outwards. Contrary to expectation, it was found that the intussusception was now easily reducible, and that a hard mass was present in the sigmoid about seven inches from the recto-sigmoid junction. Nothing suggestive of this mass had been felt at the first operation, presumably because of the large amount of oedema present. No glands were discovered in the sigmoid mesentery. After careful packing off of surrounding structures the suspicious portion of the sigmoid was excised, together with its mesentery, and an end-to-end anastomosis performed with Dulox catgut. The abdomen was closed without drainage.

The patient got on well, and three weeks later, having changed his mind as regards surgery, expressed a wish that his colostomy should be closed. This was done by Greig Smith's method, without opening the peritoneal cavity. Flapine solution was used at the operation to prevent infection of the tissues. The wound kept clean, but at the end of eight days a small faecal fistula made its appearance, which has since closed. Since the closure of the colostomy the bowels have been regularly opened without any gripping pain, and for some time past without any purgatives.

Examination by my colleague Dr. Donaldson of a portion of the mass in the sigmoid shows a typical columnar-celled carcinoma.

The chief points of interest in this case are:

1. The very long duration of the intussusception—over a year. This, of course, depends on the patient's story, but there seems no reason to doubt this, as he is a most intelligent man.

2. The slow growth of the sigmoid carcinoma, if we grant the fact that the growth was the primary cause of the intussusception.

3. The marked effect that drainage of the intestine above the intussusception had in decreasing the size of the intussusception, making its reduction possible.

4. The advisability of suspecting the presence of some

growth in all cases of large-gut intussusceptions in adults. It is often quite impossible to palpate a neoplasm in the intestine at operation because of oedema of the parts.

In my opinion all such cases should be re-exposed when the patient has recovered from the acute symptoms.

## QUININE IDIOSYNCRASY AND CINCHONINE.

BY

WILLIAM FLETCHER, M.B., B.Ch.,

AND

E. A. O. TRAVERS, M.R.C.S., L.R.C.P.

(Institute for Medical Research, Kuala Lumpur, Federated Malay States.)

IDIOSYNCRASY to quinine is much less common than one would gather from the textbooks. One of us has been in the Malay States for twenty years, and the other for more than thirty-five; but, though it is a very malarious country, the only case of pronounced idiosyncrasy to quinine which we have encountered is the patient who forms the subject of this note. Even in this instance there is some doubt whether her illness, which resembled exfoliative dermatitis, was due to quinine or to some other cause. During the war we treated large numbers of soldiers who had contracted malaria in all quarters of the world, but saw no similar cases.

MacGilchrist has shown that the several alkaloids of cinchona differ in their toxic properties, and Acton claims that the members of the laevo-rotatory group, which includes quinine, have different therapeutic properties from those belonging to the dextro-rotatory group, which comprises cinchonine and quinidine. As our patient was quite unable to take quinine and was becoming dangerously ill from malaria, we determined to try an alkaloid belonging to the latter group, and we gave her cinchonine base, with the happiest results.

One can hardly suppose that, in every case of quinine idiosyncrasy, the sensitiveness is limited to one or other of the cinchona alkaloids, and does not extend to them all; but in this instance, no sooner was cinchonine substituted for quinine than the swelling of the face and limbs subsided, the vomiting ceased, and the patient recovered.

A lady, aged 30, weighing between 7 and 8 st., became infected with benign tertian malaria and was taken ill on June 10th, 1922. On June 15th she was admitted to a nursing home, where she was treated by the medical officer with large doses of quinine. She received 30 grains of the bihydrochloride by intramuscular injection every day for three days; subsequently she was given 45 grains of quinine daily, in a mixture containing 15 grains of quinine sulphate and 3 minims of liquor arsenici hydrochlorici in each dose. On July 1st she left the nursing home, but continued to take the mixture for several days.

On July 5th, three weeks after she had commenced quinine treatment, a blotchy rash appeared, especially on the exposed parts of the body—the face, neck, arms, and hands. This rash persisted with varying intensity, until the writers met in consultation on August 31st, eight weeks after its first appearance. In the meantime malaria parasites, which were now of the subtertian variety, had been found in her blood on several occasions, and, with the exception of an interval of seven days, she had been taking quinine.

The condition at the time of our consultation was as follows: The skin over the whole body was swollen, red, dry, and peeling. The face was bloated, the eyelids were so swollen that they could hardly be opened. The lips were protruding, reddened, blistered, and cracked. There were small bullae and vesicles about the mouth. The tongue and buccal mucosa were red, peeling, and sore. The throat was inflamed and painful. The general appearance at once suggested exfoliative dermatitis due to arsenical poisoning. The patient's temperature was 102° F., and there were subtertian parasites in her blood. She was taking 10 grains of quinine bihydrochloride, in solution, three times a day, but she vomited after almost every dose.

From August 31st she was given 16 grains of cinchonine base (Messrs. Howard and Son) every day, in doses of 4 grains dispensed in gelatin capsules, and its absorption was checked by daily examination of the urine. The vomiting ceased at once, the temperature came down, the malaria parasites disappeared from the blood, the rash and swelling subsided, and within a few days the patient was up and walking about. The disappearance of the rash was followed by very definite pigmentation of the skin—it looked like dirty skin—not on the abdomen, as in arsenical poisoning, but more particularly over those exposed areas where the inflammation had been most acute.

The cinchonine was continued for several weeks, and then the dose was reduced to 8 grains daily. On one occasion, in October, the patient had a slight attack of fever with swelling of the eyelids, but it quickly subsided on resuming the original dose of 16 grains daily. The dose of cinchonine was once more dropped

to 8 grains a day in November, and on two or three days none at all was taken; a relapse of subtertian malaria occurred on November 26th, which was quickly controlled by increasing the dose.

The patient left for England on December 1st, and was in good health when we last heard of her.

## THE PULSE PRESSURE IN EXOPHTHALMIC GOITRE.

BY

I. HARRIS, M.D.,

HONORARY PHYSICIAN IN CHARGE OF CARDIOGRAPHIC DEPARTMENT,  
NORTHERN HOSPITAL, LIVERPOOL.

The height of the pulse pressure (the difference between systolic and diastolic pressure) is usually influenced under normal conditions by two factors—the height of the systolic pressure and the pulse rate. The higher the systolic pressure the more pronounced is the pulse pressure; the more frequent the pulse rate, the smaller the pulse pressure.

The systolic arterial pressure is usually increased in exophthalmic goitre, although in cases where symptoms of heart failure manifest themselves it may become lower than normal; but the most striking feature in exophthalmic goitre is the relation of pulse rate to pulse pressure. As is well known, the pulse rate is increased in exophthalmic goitre. A frequent pulse in any other condition is usually accompanied by a small pulse pressure. In tachycardia due to bacterial toxins acting on the heart muscle and other forms of myocardial trouble, and in cardiac neurasthenia and heart failure, etc., the pulse pressure is small, usually less than 40 mm. Hg. In rapid heart action due to amyl nitrite and atropine the pulse pressure is likewise diminished.

The following table records the various pressures in cases of exophthalmic goitre:

Initial.	Blood Pressure			Pulse Rate.		Initial.	Blood Pressure.			Pulse Rate.
	S.	D.	P.				S.	D.	P.	
M.	125	80	45	130		S.	120	80	40	120
E.	140	70	70	140		W.	138	67	71	160
C.	140	80	60	120		S.	165	95	70	†
J.	125	75	50	100		G.	170	85	80	120
C.	115	50	65	60		R.	170	95	75	90
D.	137	80	57	90		S.	140	80	60	120

S. = Systolic pressure; D. = Diastolic pressure; P. = Pulse pressure.

\* Pronounced cardiac dilatation.

† Auricular fibrillation.

So far as I am aware it is only in thyroidism that there is both an increase in pulse rate and at the same time a high pulse pressure. In some cases of irritable heart with manifest signs of thyroidism pulse pressure is also increased. This fact is of value in the differential diagnosis between thyroidism and other conditions. It is also important from the point of view of treatment. I have shown elsewhere<sup>1</sup> that digitalis increases the pulse pressure. Obviously this drug is not indicated in a condition where the pulse pressure is already high.

The electro-cardiograph reveals still another characteristic sign of exophthalmic goitre; the P wave is usually exaggerated in this condition, suggesting hypertrophy of the auricle. A similar electro-cardiographic condition is found in mitral stenosis, and it is significant that exophthalmic goitre, too, predisposes to auricular fibrillation.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### SUPPRESSION OF URINE AFTER LABOUR.

SUPPRESSION of urine after labour is apparently very rare, and is not even mentioned in most obstetric textbooks. I have inquired of several medical practitioners—some of them of thirty-five years' experience—and find that none of them have ever seen a case. The following may therefore be of interest.

Mrs. G., aged 30, had the following obstetric history. She was married in 1916, had a miscarriage in May, 1917, a full-time child in May, 1918, a full-time child in August, 1919, a two-months miscarriage on January 30th, 1922, and twins on February 4th, 1923. I attended her on all occasions except the first miscarriage; in 1919 I attended her continuously for the last two months of her pregnancy, and feared acute phthisis, but, to my surprise, she improved and got apparently quite well after the birth of the child. During her last pregnancy she complained of vague symptoms, most of them nervous, but there were no physical signs, and she appeared in better health than ever before. Repeated requests for a specimen of urine, however, were made in vain (a not uncommon event in general practice), so that I cannot be sure as to the state of the renal system.

On January 20th, 1923, I examined her and diagnosed a twin pregnancy. On February 4th I was sent for by the midwife because "the placenta had not arrived after forty-five minutes," a child having been born. On examination I found that another foetus was present in the uterus; it was presenting transversely, and there was prolapse of an arm. With the help of a colleague who gave chloroform, I performed internal podalic version. Both twins lived; there was little shock after the manipulations, and the haemorrhage, though rather free from a flabby uterus, was not alarming. On the following morning I was told that the patient had had continuous bilious vomiting, and she was still retching. I hoped that this was due only to the anaesthetic, but I noticed that there was extreme oedema of the eyelids, and the patient told me that "everything was a mist before her." There was no headache—which I mistakenly took to be a good sign. The same day, at 6 p.m., I was informed that the patient had passed no urine, and on discovering that there was no distension of the bladder, the seriousness of the situation was apparent. I passed a catheter, but found, as I expected, that not a drop of urine was obtained. Later in the evening, after appropriate treatment, the patient looked and said that she felt better; the oedema of the eyelids had improved, and she did not complain of headache. The following morning, however, when I saw her at 8.45, she was unconscious, breathing stertorously, the pupils were pinpoint, and she died an hour later—forty-one hours after labour was completed. There was no headache nor convulsion at any time. No urine had been passed.

The vomiting was uncontrollable by drugs, and none of the usual measures, such as hot blankets and bottles, hot steam, cupping of the kidneys, pilocarpine, etc., had the slightest effect. No post-mortem examination was obtained.

In view of the feared development of phthisis the possibility of a tuberculous focus in the renal system is suggested, though there was nothing to lead me to suppose this during her pregnancy, when, as I have remarked, she appeared in better health than ever before. However, as I did not have the opportunity of examining the urine, I cannot be definite on this point. The urine was normal on all other occasions on which I had examined it.

AMBROSE W. OWEN, M.D., B.S.Lond.,  
Honorary Surgeon, Aberdare and District General Hospital.

#### TRAUMA AND APPENDICITIS.

THE reports of cases under this heading (January 6th and 13th) induce me to record a similar case which came under my observation at the Marine Lines War Hospital, Bombay, in 1920.

A young clerk was hit by a ball over the right iliac fossa while playing hockey. He was admitted into my ward the next morning suffering from a typical attack of acute appendicitis. He refused operation at first, but submitted to it a week later, when the pain and swelling had increased. At the operation the caecum and the terminal ileum were found matted into a hard lump, with the tip of the appendix projecting about the middle. This last was removed by examination, and a drainage tube was tied in. The patient made a good recovery after some days of suppuration. Microscopic examination showed a sclerosed appendix with the lumen obliterated.

B. P. SARAWALA, F.R.C.S.F.,  
Major I.M.S. (Retd.).

Bombay.

## Reports of Societies.

### OPERATIONS ON THE ROUND LIGAMENTS.

At a meeting of the Edinburgh Obstetrical Society on March 14th, with the President, Dr. LAMOND LACKIE, in the chair, Dr. HAIG FERGUSON read a communication on the relative merits of operations on the round ligaments for retroversion of the uterus, with a suggestion for a procedure for increasing the scope and usefulness of the Alexander-Adams operation.

The operation of ventrofixation should, he considered, be reserved for women beyond the child-bearing age, or who had been rendered sterile by the removal of the tubes and ovaries for disease. Operations which utilized the round ligaments were now generally regarded as being the best means of keeping the uterus forward in women of child-bearing age. The speaker discussed the structure and function of the round ligaments, and pointed out that under normal circumstances they were under no tension and were quite slack when the uterus was lying anteverted. They did not keep the uterus forward by mere traction, but acted, so to speak, as a delicate hair-spring, and, when of normal length, by their gentle restraining action on the fundus just kept up the balance of anteversion which enabled the intra-abdominal pressure to act on the posterior uterine wall. The latter was the main factor in keeping the uterus forward, but associated with it was the action of the utero-sacral and broad ligaments. If the uterus became retroverted, the round ligaments became abnormally long, so that before they could again resume their normal function not only had the uterus to be replaced but the ligaments had to be restored to their usual length. The strongest portions of the ligaments were those within the abdomen. Further, the operation adopted should not lead to difficulty, either during pregnancy or parturition, and should stand the strain of childbirth. The Gilliam operation utilized the strongest portion of the ligament, but left three pockets in the anterior portion of the pelvis through which a coil of intestine might become entangled—although the speaker personally had never seen that accident occur. That could be obviated by the method of passing the perforating forceps between the layers of the broad ligament. This, however, was liable to lead to haematoma of the broad ligament, owing to injury of one of the veins. Moreover, he had seen several cases of recurrence after this operation, two of them after pregnancy. The Baldy-Webster operation was open to the objection that it utilized the weak portion of the ligament, and it was doubtful whether it would withstand the strain of subsequent pregnancy.

The extra-peritoneal method of shortening the round ligament (Alexander-Adams operation) had fallen into disfavour, partly on account of its limited scope, partly because of the difficulties sometimes experienced in finding the ligament, which had discouraged many operators, and because it allowed no visual examination of the pelvic organs. The last difficulty could be largely discounted by a careful bimanual examination, if necessary under an anaesthetic, which enabled an experienced gynaecologist to get an accurate idea of the pelvic condition. The operation was contraindicated by any pelvic complication, such as a fixed retroversion or diseased tubes or ovaries. If the retroverted uterus, though not fixed, was large and heavy and with a tendency to prolapse, preliminary treatment by pessary or otherwise (for example, curettage, trachelorrhaphy, perineal repair, etc.) was usually advisable before resorting to the operation. A prolapsed ovary was not necessarily a contraindication to the Alexander operation, for the ovary was usually raised up when the uterus was replaced. The results of the operation in the speaker's hands had been so uniformly good that he strongly felt that its usefulness should if possible be extended. In a series of 100 cases, all done within recent years, he had seen no instance of recurrence of the displacement even after pregnancy. He had only once had to open the abdomen after an Alexander operation, and that was for an ovarian cyst. It was the only operation which resulted in a natural pull on the ligaments and was therefore anatomically and physiologically the most correct.

Dr. Haig Ferguson then described a combined intra- and extra-peritoneal operation which he had found successful, and which, he submitted, removed all the difficulties and limitations of the Alexander-Adams operation while retaining its advantages.

A transverse incision was made two fingerbreadths above the symphysis pubis, extending down to the aponeurosis. The upper and lower flaps were detached from the latter, and a vertical incision was made either in the middle line or paramesially through the aponeurosis and, after separating the recti, vertically through the peritoneum. Any intrapelvic complication was then dealt with as required. The lower skin flap was now reflected still more, and pulled downwards by a retractor. The external abdominal rings were then defined, and the round ligaments pulled out and shortened as in the ordinary Alexander operation. If there was any difficulty in finding the ligaments in the external abdominal ring they might be caught by a pair of forceps inside the abdomen and gently pulled on by an assistant, which rendered their recognition easy. The operator could either sew up the peritoneum, recti muscles, and aponeurosis before fixing the ligaments in the inguinal canal, or preferably he could suture the round ligaments first, before finally closing the abdomen.

This operation was so simple and satisfactory that Dr. Haig Ferguson was now inclined to recommend it in all cases, complicated or otherwise, in which an operation for retroversion was indicated.

Dr. FORDYCE had long since given up the Alexander-Adams operation because of the frequent difficulty experienced in finding the ligament. He had never seen bad results follow the Gilliam operation, although there was sometimes a great amount of pain immediately after it, which he thought was due to strangulation of the loop of ligament pulled through the rectus sheath.

Professor B. P. WATSON thought that the symptoms complained of in retroversion were frequently due to a slight associated prolapse, and any operation for simply fixing the uterus to the front was, therefore, in such cases inadequate. He agreed with Dr. Haig Ferguson that the pelvic floor should in such cases be repaired. The operation which he used was a modified Gilliam, and he had never seen the haematoma in the broad ligament referred to by Dr. Haig Ferguson. A recurrence after pregnancy did not necessarily mean a failure of the operation. The patient should be examined in the puerperium and, if a retroversion were found, replacement followed by pessary treatment would result in a cure.

Dr. R. W. JOHNSTONE pointed out that the association of the round ligaments with the uterus was a mere accident of development. He had lately preferred the sling operation because of the pain so frequently experienced after Gilliam's operation, although this might be to some extent obviated by making a large opening in the rectus sheath. He had seen Dr. Haig Ferguson carry out his operation, and considered it a great advance on the original Alexander-Adams. Miss HENZFIELD used the sling operation and so far had found it satisfactory, though she was unable to say how it bore the strain of pregnancy.

Dr. H. S. DAVIDSON had met with recurrences after Gilliam's operation, and he had sometimes had to operate to remove the stitches in the loop of ligament because of the excessive pain. He had generally used linen thread. Dr. JAMES YOUNG had also seen cases develop considerable pain even after the use of catgut. He thought this was one of the chief drawbacks of the Gilliam operation. The President hoped that the routine examination of puerperal women would soon almost entirely obviate the need for operations of any kind for the cure of retroversion. He relied upon a modified Gilliam's operation, and had also seen occasional pain at the site of fixation of the ligaments, though it always passed away after a short time.

Dr. HAIG FERGUSON, in reply, said that he had also had experience of pain after the Gilliam's operation and had seen painful swellings over the anchored round ligaments; in one case the ligaments had apparently partially slogged. There had been no complaint of pain after the combined operation he had described, neither had he ever found it after the Alexander-Adams operation.

### CROUPOUS PNEUMONIA IN CHILDREN.

A JOINT meeting of the Liverpool Medical Institution and the Manchester Medical Society was held at Liverpool on March 22nd, with the President of the Institution, Professor J. HILL ABRAHAM, in the chair, when Dr. H. T. ASHBY read a paper on croupous pneumonia in children and its complications. He said that croupous pneumonia was a common disease at all ages of childhood after about the ninth month, before which age bronchopneumonia predominated. Croupous pneumonia might be classified according to the time when the physical signs made their appearance. These might be present at

once, they might at times be delayed for a day or two, or they might never be present at all. The diagnosis of the last type was made by the history of the sudden onset, the cough, the rapid breathing, the high temperature, which kept up, and the general look of the child. Fever of obscure origin in children often turned out to be croupous pneumonia. The delirium and convulsions during a severe attack of pneumonia, especially in highly strung children, were sometimes so marked that the disease was diagnosed as meningitis. The progress of acute croupous pneumonia in children was good in uncomplicated cases, and even in the so-called chronic pneumonia the outlook was good. Tuberculosis was a rare complication of pneumonia. There was no complication to rival empyema in frequency and in seriousness. It should be a golden rule, said Dr. Ashby, to explore any doubtful case, and if pus was present the earliest possible moment for its evacuation was essential to get the best results. Empyemata in older children did well with the ordinary operation, although there was often a tedious recovery and a weak lung for the future. Empyemata in young children under two years of age did very badly, and that was where some new treatment was needed. The method of aspirating the empyema seemed to give the best results, and it had the advantage that the child began to take food well and to gain strength, even though the usual open operation had to be resorted to later. The pneumococcal empyemata did better, as a rule, than any other kind.

#### Injuries to the Cervical Spine.

Mr. GEOFFREY JEFFERSON read a short paper on injuries to the cervical spine, confining himself in the main to those cases where concomitant nerve and spine injuries were not present. He said that during the last forty years it had been learnt how to recognize, and usually accurately to diagnose, vertebral fractures of the lower thoracic and lumbar vertebrae, even when the fracture involved the bodies of the vertebrae alone and the spinal canal was in no way encroached upon. In 1891 Kuemmell had drawn attention to spinal deformity resulting from previous injury. The clinical picture resembled healed spinal caries, but the clinical histories were, of course, quite different. Not so much attention—indeed, very little—had been paid to the very similar cases which were seen not uncommonly in the neck. These, again, were sometimes compression fractures, sometimes dislocations. Mr. Jefferson referred to the pathological anatomy of the injuries and to the conditions found at autopsy in the fatal cases. Most careful x-ray examinations were necessary for the diagnosis, and the speaker referred to certain fallacies in the clinical examination of these subjects. As for treatment, his figures showed a greatly improved mortality rate over that usually quoted, but that was, he said, not due to any special excellence of treatment, but rather to improvements in diagnosis which led to the recognition of the slighter cases, these reducing the percentage of deaths very considerably. The death rate in cases with complete physiological division of the cord at a high segment would probably always be enormous. Mr. Jefferson counselled against laminectomy in cervical injuries—at all events in the early stages—and pinned his faith to reduction of the broken or dislocated bones and immobilization.

#### Urticaria.

Dr. G. H. LANCASHIRE read a paper on urticaria. He dealt especially with the treatment of the chronic form in adults, laying stress on the importance of an initial rest, bodily and mental, in addition to diet and drugs. The value of the skin protein reaction appeared doubtful. Clothing was a matter of importance, and, in fact, success was only obtained by attention to detail in many directions, the cause of the trouble being often complex, including a psychic factor.

### SYPHILIS AND MARRIAGE.

At a meeting of the Medical Society for the Study of Venereal Diseases, held on March 23rd, Dr. AMAND ROUTH, by request of the Council, read a paper on syphilis and marriage. He said the association of these two should never occur if syphilis was to be eradicated, but the nation did not yet realize the importance of preventing marriages of infected persons. Doctors were powerless to enforce their warning to a patient not yet cured if he or she insisted upon marrying, owing partly to his desire to avoid the breach of professional confidence, but also because the law of libel did not protect him, especially as regards making such communications

"privileged," even between doctors. Communications between the doctor and a husband about his wife, or with a wife about her husband, were "privileged" even in venereal cases, but such a communication would usually be very indiscreet without the patient's consent.

One of the questions still undetermined is as to how long a man should be kept under treatment and observation before being allowed to marry. Before the discovery of the spirochaete and the Wassermann test (1905) it was easy to treat a wife by mercury pills, if the husband admitted a previous infection, without the wife having to be told that her still-births, for instance, were associated with her own infection. Treatment by salvarsan, especially during pregnancy, made it very difficult to prevent the wife knowing this. In these cases the doctor should avoid telling the wife the real cause of her dead children, and should try to get the husband to tell the wife of the need for treatment to enable them to have healthy children.

Dr. Routh then discussed the question of compulsory notification and the proposal to introduce health certificates for both partners as regards fitness for marriage. He showed that the investigations which might be required to certify the absence of venereal disease were the main cause which held up the proposal to have such health certificates organized. He suggested that it might be possible legally to insist upon both partners obtaining a life insurance policy which would be a guarantee of health. In poor or pauper patients this would involve State aid. He alluded to the matrimonial laws, which determined that where a wife established the fact that she was suffering from a venereal disease, and had been faithful to her husband, she could get a divorce if she could prove that her husband had acquired the disease after marriage, for the infection would be a proof, not only of legal cruelty, but also of adultery. If the disease had been acquired before marriage, and was conveyed "knowingly or negligently," it would constitute "legal cruelty" but not adultery, and the woman could only obtain an order for judicial separation, which, as the Royal Commission states, is a very inadequate remedy.

As regards treatment during marriage, the results of mercury before 1905, especially during pregnancy, in the form of hydrarg. perchlor. 1/16 grain thrice daily, were sufficient almost always to ensure a healthy child and Dr. Routh said that children thus treated over twenty years ago had remained healthy and normal till now. It was thought necessary to repeat the treatment during each succeeding pregnancy, for as the woman showed as a rule no symptoms she was thought to be free from personal infection, and it was believed that the infection was directly conveyed to the ovum by the husband's seminal fluid. It was now assumed that if a woman had a syphilitic child she was herself infected. The question whether a child could be directly infected by the father's seminal fluid as an alternative to the infection being derived from the maternal blood was still uncertain. As it was now known that the spirochaete both spontaneously and as a result of various agents broke up into small granules, it was easier to understand conceptional syphilis, but further research was required.

In his presidential address to the Harveian Society in January, 1918, Dr. Routh had stated his belief that nature provided chemical products arising at the junction of the maternal and foetal portions of the placenta, which were capable of granulating the *Spirochaeta pallida*, and by controlling the biological activity of the granules preventing them from sprouting. He suggested that this action would render the infection latent during the pregnancy in both mother and child. After the pregnancy the chemical products gradually disappeared, and the granules might spread and develop into the mature organism, which would become generalized and clinical syphilis would declare itself. If maternal treatment was adopted during pregnancy whilst the infection was being controlled and kept in the latent form, the offspring in 90 per cent. would be healthy. The latency of syphilitic infection in pregnancy was now accepted, and the possibility of there being an earlier stage in the development of the mature spirochaete was also believed in by many. It was now known, however, that both mother and child must be treated after the birth to ensure the good result now being obtained.

In conclusion Dr. Routh hoped that the Commission recently appointed by the Minister of Health would expediently consider what further steps could be taken to prevent infection.

marriages, and also to prevent congenital syphilis by ensuring more efficient medical supervision of pregnant women, and by making expert venereal treatment more generally available when indicated.

### CARDIFF MEDICAL SOCIETY.

A CLINICAL meeting of the Cardiff Medical Society was held on March 13th, with the President, Professor E. J. MACLEAN, in the chair, when Dr. H. GORDON GREAVES gave a demonstration of gas-oxygen-ether apparatus and its uses. Dr. Greaves reviewed the history of anaesthetics, and pointed out that it was largely owing to Howitt and his great scientific and mechanical skill that it became possible for "gas and oxygen" to be applied to everyday surgical use. The war gave an enormous stimulus to anaesthetic and surgical procedures, and, in his opinion, the best of the present day types of apparatus was that devised by Mr. Boyle. The dangers of gas and oxygen were few, and the advantages were enormous, because very ill patients recovered quickly from its effects, feeble and septic patients did well, long operations could be undertaken with very little risk, and nausea and vomiting were less likely to follow.

Dr. IVOR J. DAVIES showed specimens from a case of small white kidney with an associated congenital hydronephrosis; death ensued from a terminal intussusception.

The patient was an intelligent small girl of 15, and the duration from the onset of symptoms to the termination was fifteen months, the last three of which were spent in hospital. There was much thickening of the peripheral arteries, with a hard pulse; the systolic blood pressure only fell below 200 mm. on a few occasions, and was generally a little higher. Albuminuric retinitis with haemorrhages was intense; a fair amount of slightly alkaline urine was passed throughout; the specific gravity varied from 1005 to 1010, and albuminuria, averaging 0.2 per cent., was constant. Acute abdominal pain came on suddenly, the abdomen becoming a little distended, and a hard mass could be felt in the umbilical region; no blood or mucus was passed, and an enema produced a small result. Consciousness was preserved almost to the end, and no convulsions nor twitchings occurred, death taking place two days later. Necropsy disclosed the presence of an intussusception of the ileum as the immediate cause of death. The right kidney was very small and weighed barely an ounce; the cortex was much diminished and almost absent in places, otherwise very little renal tissue was left, the gland being almost entirely occupied by a uniform dilatation of the calyces. The left kidney weighed three ounces, and was triangular in section; the distinction between cortex and medulla was almost entirely lost; the pelvis was slightly and the

detached the microscopic he right kidney suggested kidney with superimposed arterio-sclerotic and chronic nephritic changes; the left kidney presented a similar picture, but the changes were less marked, producing the retinal condition. Two months before the patient died the fundi showed typical albuminuric retinitis, with a star of exudate on the macula, and many scattered small round foci of exudate over other parts of the fundi; one or two small haemorrhages were present in one eye near the disc. A month later the condition was much the same.

Mr. J. W. GEARY GRANT showed a girl, 18 years of age, with multiple swellings over the face, arms, trunk, and buttocks. The diagnosis lay, he thought, between multiple haemorrhagic sarcomata of the skin, endotheliomata, naevi, and an unusual form of von Recklinghausen's disease. A section through one of the swellings showed a predominating connective tissue element, with myxomatous change and evidence of oedema.

Mr. J. BERRY HAYCRAFT showed a specimen of bone formation in a laparotomy scar.

A laparotomy was performed on a pensioner, aged 33, and four months later a lump was noticed in the centre of the scar; it was painful and gradually got bigger and became tender on pressure. The tissue in the centre of the scar was found, on operation, to consist of a hard mass in the rectus muscle, and deep to this was a thin plate of what appeared to be bone lying between the peritoneum and the rectus muscle. Sections of this showed the presence of true bone with Haversian systems.

Professor E. EMMS-ROBERTS pointed out that actively proliferating fibroblasts could, as a result of environmental stimulus, give rise not only to ordinary fibroblasts, but, under certain circumstances, to myxoblasts, chondroblasts, and osteoblasts; the variants resulting from the alterations in the types of intercellular material secreted by the cells concerned. In this case the fibroblasts had developed directly into osteoblasts, without any indication of intermediary

forms, in a manner similar to the development of membranous bone.

Mr. J. W. TUDOR THOMAS showed a case of embolism of the central artery of the retina.

The patient was a young man, aged 27, who had suddenly become blind in the right eye; the fundus showed a dark red macula, with a large area of greyish-white retina around, in which the arteries were visible only as lines. Seventeen days after the onset of blindness the patient was able to count fingers at about a metre, but there was an absolute central scotoma. Examination of the heart did not reveal any murmurs, and it appeared to be normal. The Wassermann reaction was negative. Although the appearances in the case were those of embolism of the central retinal artery there was no clinical evidence as to the source of the embolism, and it might be that the condition was due to spasm of the retinal arteries, with subsequent thrombosis.

### TREATMENT OF VENEREAL DISEASES.

A MEETING of the Section of State Medicine of the Royal Academy of Medicine in Ireland was held on March 23rd, with the President, Dr. T. HENNESSY, in the chair, when Dr. T. P. C. KIRKPATRICK read a paper on the work of a venereal disease treatment centre. He described the procedure adopted at the venereal diseases treatment centre opened at Stevens's Hospital in January, 1919, under the auspices of the Corporation of Dublin and the Local Government Board. In the four years ending December 31st, 1922, 4,222 patients presented themselves at the clinic, of whom 743 were women and children; of these women and children 355 were suffering from syphilis. The treatment relied on was the intravenous administration of novarsenobillon, given in weekly injections over a period of eight weeks, during which time 4.05 grams of the drug were given. Subsequent treatment was guided by the condition of the patient and the blood Wassermann reaction. The results on the whole had been satisfactory, and out of the 78 patients with syphilis who presented themselves at the women's department in 1919, eleven had given birth to healthy children subsequent to treatment. The results of the treatment were illustrated by charts showing the treatment given and the blood Wassermann reactions.

Sir ARTHUR BALL said that it had been found necessary to make the centres as attractive as possible for the patients, in order to make sure that they would attend for a sufficiently long time and give themselves a chance of being cured. He thought Dr. Kirkpatrick had done well in stopping giving injections of mercury owing to the pain caused by them, though he personally was rather a believer in giving mercury at the same time as arsenical injections. In former days the patient had rather shirked the injections of mercury, but now this difficulty had been, to a large extent, got over by administering it intravenously.

Mr. A. CHANCE dealt with the general organization of the centre, and with the treatment and diagnosis of the various cases. The most difficult thing, in his opinion, in the treatment of cases of gonorrhoea was making the diagnosis, particularly in chronic cases, when success depended entirely upon the diagnosis. They had not had any complaints from patients about being written to regarding regular attendance for treatment, though he was sure that the letters were sometimes opened by people other than those for whom they were intended, but the forms were worded in such a way as not to give any information to anyone except the person to whom they were sent.

Sir JOHN MOORE did not think that they were yet in a position to make any statistics as to the effect of the more recent treatment of syphilis on the after-effects of that disease.

Dr. ELLA WEBB, Dr. W. D. O'KELLY, Dr. W. M. CROFTON, Dr. W. BOXWELL, and Dr. G. E. NESBITT continued the discussion, and Dr. KIRKPATRICK replied.

A REUTER'S telegram from Simla, dated April 7th, states that plague is epidemic in almost all the provinces of India. Statistics for the week ending March 24th show about 9,000 cases for all India, of which 8,000 resulted fatally. The epidemic is said to be worst in the United Provinces, the Punjab, the Central Provinces, the Bombay Presidency, and Delhi. In the principal towns 131 died in Bombay city, 150 in Delhi, and 48 in Rangoon. In the Sialkot district of the Punjab and the Azamgarh district of the United Provinces, the deaths numbered over a thousand each. Bengal is almost free, though there were three cases, all fatal, in Calcutta during the week.

## Reviews.

### ORTHOPAEDIC SURGERY.

THE mere names of the authors of *Orthopaedic Surgery*<sup>1</sup> are enough to guarantee that the book should be worthy of our serious attention. The name of ROBERT JONES is closely associated with the best work on deformities and disabilities in this country both in peace and war, while Dr. R. W. LOVETT has been long well known on both sides of the Atlantic as the joint author of Bradford and Lovett's *Orthopaedic Surgery* and of many valuable monographs. It is, therefore, safe to presume that we have here all that is best in orthopaedics in Britain and the United States. The opinions expressed in the book are common to both writers, and there is little internal evidence of the difficulties which must have occurred in their collaboration when separated by some three thousand miles. In a few instances, however, it is distinctly stated that such and such an opinion is that of the British or of the American author only.

In defining this special department of general surgery, as they prefer to consider it, the authors group their subjects under six headings, which it may be as well to quote at the outset. Those are:

1. Joints and their affections.
2. Bones and their affections (including ununited and malunited fractures).
3. Disturbances of the neuro-muscular mechanism.
4. Congenital deformities.
5. Static and other acquired deformities.
6. The principles and details of apparatus.

This statement at once shows how difficult it is to draw up any satisfactory definition of orthopaedics; for at least four of the above headings, if understood literally, would include a great deal more than the most enthusiastic specialist would think of claiming. The facts that the *Journal of Orthopaedic Surgery* has been renamed the *Journal of Bone and Joint Surgery*, and that more than three-fifths of the work now under notice are devoted to those same subjects, afford evidence of the direction in which the specialty has widened of late years. The good results which have been attained in special orthopaedic hospitals in the treatment of tuberculosis of the bones and joints amply justify this extension of the field.

No attempt is made in this book to discuss various methods of treatment and to weigh their merits; the authors have wisely, as we think, decided to use the space at their disposal to set forth the views of pathology which have seemed to them most sound and to describe the methods of diagnosis and treatment which they have found to be the most satisfactory.

It is not possible within the limits of a review to touch upon all the subjects in such a book as this, but an impression of its merits may be conveyed by reference to salient points of interest.

The first chapter, on the anatomy, physiology, and general pathology of joints, is a valuable one, for it gives in short space a clear and philosophic survey of the phenomena which occur in and around an inflamed articulation, and lays a good foundation for subsequent discussions. Of late years operations for the repair of ruptured ligaments have been introduced, and the best methods of performing them are described, but in the case of the crucial ligaments of the knee the reader is warned against operating in recent cases. The section on displacements of the semilunar cartilages is, as might be expected, practical. The surgeon is advised when in doubt to remove the whole cartilage. The important question of fibrous ankylosis and of adhesions in and around joints is fully discussed and excellent advice given as to when and in what circumstances they should be broken down, and when all hopes of mobility are abandoned in what position the stiff limb is most likely to be useful to the patient. It is interesting to find that the authors' views on arthroplasty are rather conservative and that they are not able to share the roseate outlook of some Continental surgeons on the results of these operations when performed upon the knee-joint. When, however, a patient is so unfortunate as to have two stiff hips a mobilizing operation upon one of them is almost imperative. In such a case it is pointed out that the

longer (if there be a difference) of the two limbs should be chosen for operation. Sir Robert Jones still performs subcutaneous osteotomy with the Adams saw in some cases of stiff hip at a faulty angle.

The authors are enthusiastic advocates of the complete open-air treatment of surgical tuberculosis. Even in the severe winter climate of Massachusetts, where the temperature of the wards or shelters is allowed at night to fall as low as 34° F., the tuberculous children have better health and fewer respiratory troubles than the "healthy" inmates of neighbouring boarding schools. Only in very young children is any exception recommended. The statistics quoted as to the bovine and human origins of infection in children bear out the contention of the authors that if the milk supply were safeguarded juvenile surgical tuberculosis would be almost abolished. Experiments are quoted showing, what has been clinically observed, that it is impossible to maintain extension of a diseased spinal column in the erect or sitting position. Both of our authors succeed in relieving diseased vertebrae from pressure and in correcting kyphoses in the recumbent position, but the American relies upon plaster-of-Paris and the Englishman on the double Thomas splint for this end. The much vaunted bone-graft treatment of Pott's disease of the spine has been tried long enough and extensively enough to enable certain conclusions to be stated. These are that in children relapses are frequent, that the operation should not be done as a routine, and that when done prolonged subsequent immobilization is imperative. In adults the procedure is generally to be recommended.

In the United States, judging from surgical and some other literature, most of the population suffer from flat-feet and nearly as many from backache, and this latter trouble is fully discussed here. Various bony abnormalities have been accused as the cause, and the sacro-iliac joint has been credited with a development and a mobility which is not observed in Europe. Even so small an inequality of the lower limbs as half an inch may apparently cause backache—or at least its correction may be followed by relief. The section on this subject is well worth study, for such cases are proverbially difficult and obstinate, and if the surgeon cannot relieve them they generally fall into the hands of osteopaths, bone-setters, and other irregular practitioners.

The United States have been the scene in the present century of several epidemics of anterior poliomyelitis, of which the last, in New York State and City in 1916, included 13,233 cases, with a mortality of 25.2 per cent. It is therefore not surprising that American physicians and surgeons should have increased our knowledge of the disease and improved its treatment, and the chapter on this subject is not the least important in the book and well repays study, but hardly lends itself to brief summary. A much needed warning is given against amputation in severe and extensive paralysis, when the resulting stump is useless because it has no muscles by which an artificial limb can be actuated. The only practical amputation in such a case is at or just below the hip-joint, and it is a mistake to suppose that there is no satisfactory artificial limb available for such a case, although its usefulness must depend upon the extent to which the trunk muscles have escaped paralysis. A patient without good muscular control of the lumbar region and pelvis cannot be expected to use an artificial limb.

Muscle training for paralysed children and others is well described and its importance duly insisted upon. Congenital deformities of all kinds, static deformities, and, last but not least, scoliosis, are adequately dealt with. In this last connexion it is of interest to note that the Abbott method of treatment by plaster jackets, for which some years ago extravagant claims were made, is dismissed in a few lines.

This book is sure to become the standard work on the subject in the language, and will probably long retain that position. It is exceedingly well illustrated, and the type is large and clear. It would be improved, however, by a much more copious index.

### THE VASOMOTOR SYSTEM.

THE appearance of Professor Sir W. BAYLISS's volume on *The Vaso-motor System*<sup>2</sup> in Professor Starling's series of monographs on physiology provides a welcome and authoritative review, by a leading physiologist who has done much pioneer research on it, of a subject closely bound up with practical medicine. The field covered is large, for not only does

<sup>1</sup> *Orthopaedic Surgery*. By Sir Robert Jones, K.B.E., C.B., Ch.M., F.R.C.S., F.A.C.S., etc., Lecturer on Orthopaedic Surgery, Liverpool University, and Robert W. Lovett, M.D., F.A.C.S., etc., Professor of Orthopaedic Surgery in Harvard University. New York: William Wood and Company, 1923. (Medium 8vo, pp. 659 + xv; 712 engravings.) To be published in this country by the Oxford University Press, price 42s. net.

<sup>2</sup> *The Vaso-motor System*. By Sir William M. Bayliss, D.Sc., F.R.S., F.R.S. Monographs on Physiology. Edited by Ernest H. Starling, M.D., D.Sc., F.R.S. London: Longmans, Green and Co. 1923. (Demy 8vo, pp. 163; 17 figures. 7s. 6d. net.)

the author describe the nerves supplying the blood vessels and their mode of action, the influence of chemical bodies, such as adrenaline, pituitrin, ergotoxin, histamine, acetyl-choline, nitrites and nicotine, on the calibre of the blood vessels, but he also discusses how the blood pressure is affected by the vascular changes and how the blood supply of individual organs is modified in response to their requirements in activity and rest.

The problem is so far simplified that the heart is assumed to be beating at a constant rate and with a uniform output. In view of Krogh's work, which is quoted, special interest attaches to the account of the circulation in the capillaries and of the part they play in the normal blood pressure. Professor Bayliss agrees that the capillaries have the power of contracting, but appears somewhat unconvinced by the evidence available that they have a direct nerve supply, and he concludes that the peripheral resistance is chiefly exerted by the arterioles. After quoting the experiments of Dale and Richards with histamine and their conclusion that the resulting fall of blood pressure is caused by decrease of the peripheral resistance in the capillary area, he expresses the opinion that this fall is mainly a capacity effect, due to the accumulation of a large volume of blood in the dilated capillary region; but, like another famous physiologist, he remarks that the subject requires further investigation.

Another question discussed in an interesting manner is whether, since the adrenals are excited by splanchnic stimulation, the normal blood pressure is maintained to any important degree by the continuous inflow of adrenaline; the evidence on this subject is conflicting, but on the whole it would appear that the amount of adrenaline in the circulation is too small to have any influence of importance in this direction. A chapter is devoted to the contractility and nerve supply of the veins, and the concluding chapter deals with the important subject of haemorrhage and shock, showing the physiological reason for adding to the fluid used for intravenous injection some colloid, such as gum acacia, having an osmotic pressure equal to that of the plasma colloids. This valuable monograph has a select bibliography and on all accounts deserves the attention of the profession.

#### GUY'S HOSPITAL REPORTS.

In the first quarterly part of this year's volume of the *Guy's Hospital Reports* the absence of any contribution from the editor, Dr. A. F. HURST, is a matter for regret, but his inspiration is evident in at least two of the twelve articles. The most considerable paper is Dr. G. W. NICHOLSON'S continuation of his "Studies on tumour formation," dealing with the importance of congenital malformations in tumour formation, in which he brings forward an elaborate argument with much evidence of thoughtful investigation to prove the error of Cohnheim's theory of the origin of all, or at least the majority, of neoplasms in cell rests. In the course of his article he concludes that cystic disease of the kidneys and embryonic renal tumours represent different end-results of the same original malformation and occur with about equal frequency; cystic kidneys are, he believes, extensively altered by accumulated secretion and thus do not represent the malformation in its original form; the embryonic tumours are simply enormous "malignant cell rests" which have always been malignant. Cutaneous melanomas arising in congenital moles—the other example that might lend support to Cohnheim's theory—arise *de novo* from the differentiated tissues of congenital pigmented moles, often at an advanced age and in response to altered environment, such as an irritant; they are not considered to support Cohnheim's view. Mr. A. R. THOMPSON discusses the clinical features of renal growths, and from analysis of 81 cases shows that the right kidney is attacked more often than the left in the proportion of 4 to 3. Professor PEMBREY, Dr. DEBENHAM, and Dr. JOFFE record their physiological observations on the excretion of urine in a case of ectopia vesicae; they did not succeed in producing diuresis by hypodermic injection of pituitrin. Mr. W. M. MOLLISON reviews 18 cases of new growth arising in the maxillary antrum or ethmoidal cells, and considers their diagnosis and treatment; reference is made to John Hilton's paper in the first volume of these *Reports* (1836) on a large bony tumour in the face completely removed by spontaneous separation; it is here reprinted. In

a charmingly written account of want of appetite and refusal of food in childhood, Dr. H. C. CAMERON shows a shrewd knowledge of the psychology of the young, and points out that refusal of food by a physically healthy child shows that his or her management is at fault. Mr. R. P. ROWLANDS considers the treatment of complete obstruction of the colon, and Dr. J. R. BELL provides a useful account of the tests for occult blood in the faeces; he recommends the benzdine test and four days' diet free from haemoglobin and chlorophyll before the stools are tested. Drs. RYLE and PASSEY show that Surrey rats may be infected with the *Leptospira icterohaemorrhagiae*, that cases of human spirochaetosis icterohaemorrhagica have thus arisen, and that this possibility should be thought of in a patient with febrile jaundice of obscure origin with pains in the limbs and haemorrhages. Dr. H. W. BARBER brings forward cases to prove that, just as asthma may be due to more than one variety of micro-organism, so urticaria and angeo-neurotic cedema may depend on sensitization to *Streptococcus longus*, *Bacillus coli*, and *Staphylococcus aureus*. Dr. GORDON GOODHART, formerly Douglas Demonstrator of Pathology at Guy's Hospital, writes a commentary on Drs. CAMPBELL and CONYBEARE'S statement in the July (1922) number of these *Reports* that in Addisonian anaemia a colour index of between 0.7 and unity is almost as common as one between unity and 1.2 and quite as common as one between 1.3 and 1.6. This is quite contrary to his experience, and with engaging tact he suggests that the Guy's figures might have been different if a proportion of them had not been based on blood counts done by clinical clerks.

#### PSYCHOLOGY AND PSYCHICAL RESEARCH.

Dr. T. W. MITCHELL has written a volume entitled *Medical Psychology and Psychical Research*,<sup>4</sup> which deals with those branches of psychological medicine which have thrown most light on the problems of psychical research—namely, hypnotism, hysteria, and multiple personalities. The author has devoted much study and clinical investigation to the various forms of dissociation, and he writes from the strictly scientific standpoint. A considerable part of the book deals with the problem of the appreciation of time by somnambules. It is well known that hypnotized subjects exhibit a remarkable accuracy in estimating time intervals, and that this power may persist into post-hypnotic life, so that an action suggested in hypnosis, to be performed in waking life after a certain interval, is generally carried out at the appointed time. It is not easy to explain this supernormal ability of somnambules, and Dr. Mitchell feels that the difficulties presented by this problem are of such a nature as inevitably, on any hypothesis, to leave a considerable residuum of unexplained phenomena. At the same time his discussion and suggestions do much to remove the mystery of time appreciation in these cases, and he makes it clear that there is no need to postulate some transcendental faculty in explanation of the phenomenon.

In further chapters the author gives a detailed account of a case of grave hysteria with recovery under hypnotic and suggestive treatment; he describes and discusses some cases of multiple personality, gives an account of the famous Doris Fischer case, and concludes by considering the bearings of the facts observed in dissociated states on the ultimate problems of personality. The book contains much of interest and importance to those who are concerned in the problems of the mind, and will well repay careful study.

#### CHRONIC DIARRHOEA.

Dr. J.-CH. ROUX says in a preface he has written for a volume by Dr. LOUIS TIMBAL, entitled *Les Diarrhées Chroniques*,<sup>5</sup> "Chronic diarrhoea is the most apparent symptomatic manifestation of many different pathological conditions, and often it is the only one noticed by the patient." This statement briefly expresses the point of view emphasized repeatedly in the subsequent pages that chronic diarrhoea must not be regarded simply as an intestinal disease or even as necessarily due to intestinal disturbance: it may be the only apparent symptom of pathological processes at work in the liver, pancreas, or kidney, or of functional disturbance of the nervous system. In the clinical examination of a patient

<sup>4</sup> *Guy's Hospital Reports*, vol. Ixxiii (vol. III, Fourth Series), No. 1, January, 1923. Edited by A. F. Hurst, M.D. Issued quarterly. London: Henry Frowde, and Hodder and Stoughton, 1923. (Hors: 8vo, pp. 116; 1 plate, 15 figures. Subscription, 2 guineas, post free, for volume of four numbers; single numbers, 12s. 6d.)

<sup>5</sup> *Medical Psychology and Psychical Research*. By T. W. Mitchell, M.D. London: Methuen and Co., Ltd. 1922. (Cr. 8vo, pp. 244; 2 pls. cr. 7s. 6d. net.)

<sup>6</sup> *Les Diarrhées Chroniques. Etude Clinique, Coprologique et Thérapeutique*. By Dr. Louis Timbal. Paris: Masson et Cie. (Demy 8vo, pp. 270; 10 figures. Fr. 12 net.)

complaining of diarrhoea the condition of all the organs of the body should be carefully considered.

The first part of the book is concerned with diagnosis—clinical examination, examination of the stools, radioscopic examination, and rectal examination. The tests described for the investigation of the faeces are all such as can be carried out with very simple apparatus and are designed to give information with regard to undigested food constituents and pathological products in the faeces.

In one instance the method advised calls for criticism. The deductions which can be drawn from the study of stained films of the faeces are not so reliable as the author declares, and it is misleading to suggest that the bacteriological examination may be regarded as complete when films only have been examined after staining with iodine and Gram's stain. The other methods described, and the table illustrating the value of chemical tests are, however, very useful. The second part of the book deals with the clinical types of diarrhoea according to their origin—functional, toxic, infectious, reflex, etc. Fermentation and putrefaction are clearly defined and differentiated. The third part deals with treatment, including diet, general hygienic conditions, and physical agencies.

It cannot be said of this treatise that its outlook is cosmopolitan. Scattered throughout its pages are references to some 290 publications; of these, 278 are from French sources and 11 from German; only to one publication in the English language does the author own his indebtedness. We commend this book, therefore, as embodying French views.

### PREVENTIVE MEDICINE AND HYGIENE.

THE issue of a fourth edition of Professor ROSENNAU'S *Preventive Medicine and Hygiene*<sup>6</sup> is full justification for the welcome we accorded the work in 1914. The author has adhered to his original grouping of communicable diseases into those, such as small-pox and venereal diseases, for which specific or special prophylactic measures are available; those spread largely through the alvine discharges, such as typhoid fever and cholera; those spread largely through discharges from the mouth and nose, including diphtheria and tuberculosis; and insect-borne diseases. In 1913 Professor Rosenau gave only qualified approval to the notification of venereal disease, and he is still of opinion that compulsory methods of notification are only partially successful, and that little may be expected from voluntary notification. He states that notification by serial number has been effective in Massachusetts since the beginning of 1918, and that in 1919 there were reported to the State Department of Public Health 9,435 cases of gonorrhoea and 4,127 cases of syphilis. While theoretically every case of venereal disease should be isolated until all danger of infection is passed, he agrees that this course is impracticable, but advocates better and more attractive hospital facilities and free beds as a means of securing voluntary isolation. He is in general agreement with those who consider that venereal diseases are both preventable and curable, and that their control depends upon early diagnosis and facilities for prompt treatment. In a neatly turned epigram he expresses a well recognized truth that gonorrhoea is the great preventer, syphilis the great destroyer of lives. A great deal of new matter has been added to the present edition, including a very informing section dealing with public health measures and methods.

After the manner of other American writers an attempt is made to assess the relative values of public health work, and it is of interest to learn that in general sanitation Professor Rosenau considers privy sanitation as nearly five times more valuable than housing and ten times more than plumbing. In child hygiene he places a high value on health visitors, whose work he considers is four times the value of infant consultations. When discussing the question of public health propaganda the author gives very sound advice, which is especially valuable when there are in the field so many amateur and irresponsible propagandists.

"It is very important," he insists, "that the facts stated should tell the truth. It is more important to be correct than to be clever. Half truths are often dangerous. Wrong teaching undermines confidence in health authorities. It is a question whether the subject is dignified by the use of circus methods or the antics of the clown."

Few writers in clothing their subject so . . . His short crisp

<sup>6</sup> *Preventive Medicine and Hygiene*. By M. J. Rosenau. Fourth edition. New York and London: D. Appleton and Co. 1921. (Med. 8vo, pp. 1567; 194 figures. 45s. net.)

sentences, his scant use of technical terms, and the apposite illustrations he makes use of to emphasize his statements add very much to the value of the work whether it is considered in the light of a textbook for the student, a book of reference for the public health officer, or a guide for the lay social reformer. The large number of well selected and excellently executed illustrations are a noticeable feature in the volume.

### NOTES ON BOOKS.

DR. BERNARD HOLLANDER has written a book on *The Psychology of Misconduct, Vice, and Crime*.<sup>7</sup> He deals with the problem from the standpoint of the "new psychology," and endeavours to present systematically, in their medical and psychological aspects, the various divergencies from normal conduct which come under the observation of the physician. He holds that many moral offenders belong to the domain of mental pathology, and that many of them are amenable to treatment by psychotherapy. He makes a number of suggestions for dealing with the criminal suspected of mental disorder, and pleads for the most careful medico-psychological study of delinquents, not only from motives of humanity and justice to the delinquent, but for the prophylaxis of future offences and the protection of society.

DR. CHARLES W. HAYWARD has written a volume entitled *What is Psychology?*<sup>8</sup> He does not use the term "psychology" in the conventional sense, and the book is not intended to be a scientific treatise. Its aim is to suggest a remedy for the "diseased psychology" of the human race, and the author unsparingly denounces the modern tendencies of the press, the drama, art, literature, society, politics, finance, and commerce. He believes that the cure of present evils will be effected if children are brought up entirely free from bad influences, and the book is largely devoted to the development of this theory. Dr. Hayward writes with sincerity, and he is evidently deeply moved by those elements in modern life which he deplores so strongly. At the same time, while fully recognizing the importance of environment in the formation of character, we do not feel convinced that Dr. Hayward has discovered what all social reformers are seeking—namely, a means of changing the heart of man. After reading this book we still feel that the millennium is a vision rather than a possibility.

The figurative expression that molecules are built up of atoms has been given a literal significance by EDWARD E. PRICE, who has devised a geometrical model to represent the carbon atom.<sup>9</sup> The conception on which the author has founded his idea is that "it is difficult to conceive of spherical or ellipsoidal forms having the power to arrange themselves according to geometric laws so soon as the vibrations of heat are reduced to a certain degree, and in the absence of any other directive force so far as is at present known, but if the atoms themselves have definite geometric forms, then arrangement in an orderly space-lattice, so as to produce definite geometric figures peculiar to each atom, appears to be the natural result of the withdrawal or reduction of the vibrations of heat." The positive origin of his deduction regarding the carbon atom is found in the crystal properties of the diamond and of graphite. It is further imagined that chemical combination takes place with the faces of the atoms in contact. A concept of such simplicity must have already occurred to a great many chemists and physicists, only to be rejected on more critical examination; had a solution or these lines been possible, progress in that direction would have been made long ago. Mr. Price has done a considerable amount of work in surveying assemblages of the parts that can be fitted, but it cannot be said that he has developed from his theme a theory upon which anything substantial may be built. His postulates are mostly extravagant. Frequently they are weak. He writes: "If it be allowed that the hydrogen atom has the form of a very oblate pyramid, it will follow that nascent hydrogen will adopt a position in which the base of the pyramid will be above and the apex will occupy the lower position. . . . In this position the hydrogen atoms will readily combine with the lower surface of the benzenoid," and so on. This mode of reasoning is not the less astonishing as it is clear from other statements that the author is acquainted with the nature of the electronic theory and its developments.

## MEDICAL AND SURGICAL APPLIANCES.

*A Dosimetric Apparatus for Intratracheal Anaesthesia.*

Dr. C. H. MOTT, Senior Honorary Anaesthetist to the North Staffordshire Infirmary, sends us a description of his modification of the ether intratracheal insufflation apparatus designed by Mr. R. E. Kelly of Liverpool. To Kelly's ether apparatus he has added 1) a device ("flowmeter") indicating the amount of air passing, 2) a chamber for chloroform in addition to the ether chamber, 3) a sight feed nitrous oxide and oxygen bottle similar to Boyle's or Gwathmey's, and 4) a water manometer for giving the respiratory index in addition to the usual mercurial manometer for showing the intra-apparatic pressure. Dr. Mott states that the most important of these additions is the "flowmeter," which has enabled the makers to place on the apparatus, above the chloroform and ether chambers, dials showing in plain figures the percentages of anaesthetic vapour added to the air stream under varying conditions of temperature and rate of flow. The chloroform and ether chambers are surrounded by water jackets to stabilize their temperatures (in accordance with the suggestion originally made by Mr. H. M. Page). The whole apparatus, mounted on a nickelled plate and fitted on a mahogany board, forms a convenient anaesthetic unit for the equipment of the anaesthetic room of a hospital, since it can be used for almost any form of inhalation anaesthesia. Dr. Mott then describes in detail the special features which distinguish his modification from Kelly's apparatus, and summarizes his personal experience of the modified apparatus during the past six years in hospital and private practice. His experience is recorded in the following table, which shows the number of times the apparatus has been employed (both for intratracheal and intrapharyngeal insufflation) and gives an analysis of some of the regions operated upon and the anaesthetic employed.

	Intratracheal Insufflation—			Intrapharyngeal Insufflation—		
	Ether.	Mixture.	CHCl <sub>3</sub> .	Ether.	Mixture.	CHCl <sub>3</sub> .
Total number of insufflations	205	361	405	76	97	80
Intra-abdominal ...	58	166	152	23	33	16
Thyroid ...	7	8	6	3	7	3
Glands of neck ...	4	13	6	3	11	13
Breast ...	4	5	12	2	4	4
Kidney ...	1	6	13	3	4	4
Piles ...	7	5	12	—	2	2

Dr. Mott acknowledges his indebtedness to the late Dr. Augustus Waller, to Dr. Dorée, and Dr. Thompson, for facilities placed at his disposal in making his anaesthetic unit a dosimetric apparatus; also to Mr. Guy Drew for collaboration in the scientific work necessary to draw up the dosimetric dials and in designing the machine. The apparatus has been made throughout by Messrs. Down Bros., Ltd., of London.

*Elevator for the First Rib.*

Mr. W. H. ROMANIS, M.Ch.Cantab., F.R.C.S. Eng., has devised a modification of the ordinary Doyen's curved rib elevator for removal of the first rib in extensive thoracoplasty to collapse a phthisical lung. Mr. Romanis's instrument differs from Doyen's

in having the hook-shaped end very short and narrow, to correspond with the ribbon-like shape of the first rib. The hook is set at a lateral twist to the shaft and is 2 inches below the line of the shank. The instrument is made by Messrs. Allen and Hanbury.

## MEDICINAL AND DIETETIC PREPARATIONS.

*Nasal Creams in Ampoules.*

We hesitate to say that any method of dispensing is new, but we have not previously seen the device which Messrs. Duncan, Flockhart and Co., 104, Holyrood Road, Edinburgh, use for dispensing nasal creams. The cream is put up in an elastic gelatin ampoule, with a long nozzle; the tip is cut and the nozzle is then introduced into the nostril, the ampoule is squeezed, and the cream expelled. Each holds enough for some dozen applications. Various prescriptions are used—alkaline, antiseptic, astringent, iodized, sedative, or stimulant. Details of the drugs used will be supplied to any member of the profession who wishes to prescribe the ampoules. They seem to us to be a very convenient and practical method of introducing medicaments into the nostrils.

## THE KATA-THERMOMETER, BODY TEMPERATURE, AND EFFICIENCY.

THE Medical Research Council has just issued a volume entitled *The Kata-thermometer in Studies of Body Heat and Efficiency*.<sup>1</sup> The very extensive observations therein contained are an advance on those published in *The Science of Ventilation and Open-air Treatment*,<sup>2</sup> by Dr. Leonard Hill. It is recognized that in securing conditions suitable for workers the wet bulb thermometer temperature is more important than the dry, and vapour pressure than relative humidity; most important of all, however, is the velocity of movement of the air, as on this chiefly depends loss of heat from the body by convection and evaporation. The body is not a static instrument like a thermometer, but dynamic, producing heat which must be lost at equal rate. The kata-thermometer measures the rate of heat loss from its surface, which is approximately at skin temperature, and evaluates the important effect of air movement. It is obvious that the more comfortable the conditions for the worker, the more contented will he be and the better work will he do. The body is fashioned for getting food by active muscular work, and upon this activity depends the proper vigorous function of the digestive and respiratory organs, and keen enjoyment of life. Hothouse conditions of life suitable for the failing power of the aged and those sinking from disease are mistakenly supposed to be suitable for the young and healthy. A traditional fear of cold is handed down, not only from mother to child, but to medical students in almost every medical textbook, and for fear of catching cold children are confined, and adults confine themselves, too much indoors and are overclothed. They are debilitated thereby and exposed at the same time to massive infection in crowded places. How utterly wrong is the still far too common medical advice to keep warm and fear all exposure is shown by the results obtained from the great degree of exposure of children, more or less naked, to the sun and air out of doors, which is practised with suitable precautions by Rollier at Leysin, Gauvain at the Treloar Hospital, and many others.

The atmospheric conditions suitable for healthy muscular activity are not those habitual to many living a sedentary monotonous life in an environment of overwarm, stagnant, and moist air; nevertheless they should approximate to the open-air conditions such as those enjoyed in playing open-air games. The breathing of cool air entails a greater flow of blood and lymph through the respiratory membrane, and as by vigorous open-air activity the volume of air breathed is increased many times the respiratory membrane is far better "washed" by open-air life and so protected from infection. Experience during the great war showed how much this improved the general condition of the city inhabitants as regards health, vigour, and efficiency. Our modern populations have purer water and more food; they are better clothed and much less drunken than a generation ago. Nevertheless the agricultural population, in spite of low wages and indifferent housing, sanitation, and water supply, have a mortality lower than the industrial population half a century ago. Moreover, while much has been done to lower the mortality of children, and to increase the average duration of life, almost nothing has been done to extend the life of the middle-aged. As Farr established fifty years ago, there is a close relation between crowding and mortality. Now the ventilation of workplaces and homes in the sense of this and the previous reports is little better, and probably in some respects worse, than it used to be. Herein lies a working hypothesis to explain why the rate of mortality at later ages does not sensibly improve. Not only does crowding lessen vigour and increase infection, but it divorces the people from the green foodstuffs which are the great ultimate source of vitamins and afford variety of proteins and salts most advantageous to growth and health. The smoke curse of the cities comes into play in lessening the desire for outdoor exercise, in robbing the body of the stimulating effect of the ultra-violet rays which are filtered off by smoke and glass, and in preventing the growth of salads in city courts, roof-tops, and gardens.

"Perhaps the mortality of adults from respiratory diseases in the north-western industrial districts of 1923 will produce upon the sanitarian of 1930 the same impression as produced upon ourselves by the history of enteric fever in England and Wales between 1850 and 1880."

<sup>1</sup> Special Report Series, No. 73. H.M. Stationery Office. Price 5s.

<sup>2</sup> *Ibid.*, Nos. 32 and 52.

More than two thousand years ago Hippocrates said that those who live in sheltered places were in general a weedy lot. "Those exposed to the cold winds must need be strong, great eaters and drinkers. They were big fellows, too, and their wounds did not suppurate and one can easily understand that such people live longer than the average." Only now are we beginning to learn the truth of this and to recognize that the balcony of a hospital is much more important than the ward for the treatment not only of tuberculosis but of rickets, wounds, pneumonia, and all febrile diseases. So, too, the garden space round a house is far more important than the house itself. People can be very healthy in the cramped crofter's cottage, while a model dwelling confining them in close warm rooms under glass can cause rickets, tuberculosis, and nervous debility.

The evidence submitted in this report goes to prove: (1) That in all parts of the world atmospheric conditions classed on the objective basis of kata-thermometric readings as unsatisfactory are, when tested by the subjective sensations, hard to endure. (2) That in every case in which subjective sensations were controllable by an objective test of industrial output the test gave proof of diminished efficiency. (3) That in the industries investigated—for example, boot and shoe, printing, pottery, and cotton industries—the mortality increases as the cooling power lessens. (4) That the basal metabolic processes of the body respond rapidly and considerably to changes of atmospheric condition, and respond in the sense predicted by the general reasoning based upon kata-thermometric measurements.

In Part I the more recent researches regarding the kata-thermometer as a physical instrument are recorded, and the information required by those who use it put in an available form. Much herein is due to Miss D. Hargood Ash's mathematical treatment. The new recording kata thermometer contrived by Dr. E. H. J. Schuster is described. This instrument, automatically alternately heated electrically and allowed to cool, writes a record of cooling rate on paper. Several kata-thermometers can be in turn connected to the recording mechanism; a manager is thus able to sit in his office and see the cooling power in any shop of his factory.

In Part II recent observations in temperate, alpine, and subtropical climates are related. Very interesting are those taken by C. Dorno at Davos, showing the moderate and uniform cooling power and high evaporative power there. Cold, dry, calm air and sunshine are the great merits of the alpine winter climate.

In Part III the use of the kata-thermometer in industry is summarized by Dr. H. M. Vernon from the numerous researches which have been carried out by the Industrial Fatigue Research Board workers in boot and shoe, printing, pottery, cotton and linen factories, and in laundries. The conclusion is reached that such systematic investigations ought to be made in all our chief industries.

"We should be firm in maintaining that the atmospheric conditions observed in the healthy trades, as indicated by statistics, ought to be imitated as far as possible in the less healthy ones, even if this means a considerable outlay in installing a better system of ventilation or more efficient machinery."

Quite apart from ethical considerations, it is probable that the initial outlay will more than repay itself in the improved health and increased efficiency of the workers. Striking examples are given from a laundry and from a textile factory of the effect of simple improvements carried out as the result of kata-thermometric measurements. Cooling powers were thereby doubled, and raised from one-half of, up to, the standard fixed for sedentary workers as a minimum.

In Part IV the conditions produced by certain different types of ventilation and heating appliances in factories are dealt with by Mr. T. Bedford and Mr. T. C. Angus. The latter also details a very interesting series of tests carried out on a large Atlantic liner. They show the inefficiency of an expensive plenum system of supplying warm air to first-class cabins, and the very great defect of third-class cabin ventilation arising from the heat of the ship and lack of adequate ventilation with cool air. It may be pointed out here that the defects are not due to chemical impurity of the air, but to defective cooling and evaporative power.

In Part V Dr. Vernon, considering the index of comfort at high atmospheric temperatures, shows the importance of the wet bulb temperature and of clothing, and insists on the special value of the kata-thermometer as a measure of velocity of movement.

In Part VI Drs. Leonard Hill and Argyll Campbell describe extensive studies of basal metabolism carried out in indoor

and outdoor conditions, with subjects clothed and stripped. Herein are included observations made at the Trelow Hospital with Sir H. Gairdner, at the English Sanatorium, Montana, with Dr. B. Hudson, at High Carley Sanatorium with Drs. Cox and Pask, at Sevenoaks Hospital with Dr. Siebel, and at the Berks and Bucks Sanatorium with Dr. Carling. The main conclusion reached is that open-air treatment increases the basal metabolism some 50 to 100 per cent., and this remains high, even when the subjects are put for some days in a warm room. This increased metabolism is regarded as an important part of the curative effect of open-air treatment. The effect of local and general cooling by water on metabolism is also considered, and it is shown how very local cooling or heating—for example, of the hands—can take away or add almost as much heat as the body produces. Most important experiments were made on working efficiency in a wind tunnel fitted with a moving platform on which the subjects ran. It is shown that during hard work the pulse frequency is lessened some thirty times a minute when the subject is properly cooled by a wind. The heart gets tired, and efficiency of the worker falls off when much of the blood has to be sent to the skin to be cooled instead of to the muscles—that is, when the cooling power is too low. In a South African mine Dr. Orenstein and Mr. Ireland found the efficiency of native workers 50 per cent. less in the galleries where the kata-thermometer readings were lowest than in properly cooled places. Another interesting research detailed in this report is on the protection afforded by clothing, wet or dry, and in particular by waterproofs, for shipwrecked people. Wet wool clothing affords considerable protection both from wind and from sea waves, and a waterproof over such wet clothing can adequately conserve the body heat. Metabolism when work was done by night instead of day was also investigated by examination of respiration and urinary excretion, and interesting conclusions reached.

The Medical Research Council has done well to produce this report, which has a direct and practical application to securing better health and greater happiness to the people, provided the necessary attention is given to the simple rules which should govern domestic and industrial life.

## ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee on March 13th 38 cases were considered and £489 voted to 35 applicants. The following is a summary of some of the cases relieved:

Widow, aged 53, of L.R.C.S. Edin. who died in 1912. His youngest daughter (aged 20) requires training to enable her to earn her own living. Applicant is at present out of a post herself but hopes to get one.

Widow, aged 60, died in 1903. Through age and infirmity she is unable to accept hospitality to visit her own home for long visit was formerly her own reduced circumstances. She is crippled with rheumatism and can only get about on two sticks. Total income £68. Rent £28. Voted £25 in twelve instalments.

Daughter, aged 65, of M.R.C.S. Eng. who died in 1873. The applicant, who is a nurse, has not been able to work since October, 1921. She failed in 1922 to get sufficient votes for Epsom College. Her only income is 7s. 6d. a week from the Nurses' Insurance Fund and occasional gifts from friends. Voted £18 in twelve instalments.

Widow, aged 37, of M.R.C.S. Eng. who died in 1922. Owing to the sudden death of her husband she is left with two children, ages 10 and 8, with an income of only £100 a year. She asks for help towards education. A small grant was made to render the applicant eligible for consideration for an education grant.

Widow, aged 32, of M.R.C.S. Eng. who died in 1922, after an illness of eight years which prevented him from working and saving. She is left with a son at school. Her only income is the interest on £200. As she is a trained nurse a small grant was made to grant.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

In these days of exorbitant prices for clothing and household necessities the Royal Medical Benevolent Fund Guild is overwhelmed with applications for coats and skirts for ladies and the girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

THE Government of Afghanistan, according to the *Mündel medizinsche Wochenschrift*, is offering inducements for German physicians to settle in Afghanistan. Ten are wanted at once in the army and in hospital and contract practice or private practice.

## Nova et Vetera.

### CUPPING, DRY AND WET.

I AM old enough to remember when venesection was in vogue; indeed, probably the very first quasi-surgical procedure at which I was privileged to assist, as the pupil of a provincial practitioner, was that of bleeding a plethoric publican. I remember his pale, puffy face, swollen abdomen, and fat, sad voice. I remember, too, that he was much pleased with the relief afforded him. Yet, curiously enough, this old-fashioned country practitioner never spoke to me of cupping, nor did anyone of my subsequent principals do so. I feel, therefore, at liberty to infer that cupping has never been generally resorted to in England, at any rate not within the last century or so.

I have now practised for many years abroad, and I have been struck by the frequency with which dry and wet cupping are employed on the Continent, and by their efficacy in relieving inflammatory and congestive states.

Nevertheless, most physicians must have, at any rate, heard of it, for at a time when I was going through the English and French curricula concurrently I remember accompanying my chief, a well known physician, round the wards in my London hospital, and when we came to a case of inflammation of the lung I happened to mention that in Paris the first thing we should do would be to apply *ventouses*, alias cups. "An excellent idea," exclaimed the physician, adding, to the other students, "this will give you an opportunity of seeing how it is done." Then, having asked for the "cups" to be brought, he turned to me and asked how we did it over there. I replied that as a rule we used methylated spirits of wine or a little cotton-wool. The patient's back having been bared he put some cotton into the tumbler, which in this instance figured as cupping glass, lighted it, *blew it out*, and applied it rapidly to the chest wall—but of course nothing happened. I saw at once that he had never before applied cups and I began to feel anxious; he, too, was a little flushed and embarrassed. I took this opportunity of slipping round to the other side of the bed so as to face him, and when he tried a second time and failed I leant forward and said, "Allow me, sir, I am perhaps better placed than you are." Taking the glass from his hand I lighted the cotton and applied it *without* blowing it out, and a triumphant success was the outcome. "You see, gentlemen," he remarked, "it's easy enough when you have the knack of it."

On another occasion, several years later, by which time I was in practice, I had occasion to call in consultation in a very grave case of pneumonia a one-time president of the Royal College of Physicians. Here again I suggested cupping, in which he cordially acquiesced, and at his request—for he admitted that he had never seen it done—I applied the cups. Thereafter my patient swore by this consultant in that he had cupped him to his very great satisfaction.

In France cupping is in such great request that every farm wench is an adept thereat. It is the universal panacea for aches and pains, for stitch in the side or shortness of breath, and so on. Among the Arabs in Algeria, where the native medicine man will trepan you as soon as look at you, cupping, especially of the temples, is very popular. Any Sunday morning in the native quarter, alongside the native dentist who is extracting teeth with a mediæval "key," is the *tonbib* with his cups, and in front of him a patient suffering from headache or loss of memory, or what not, with several long narrow cupping glasses projecting from his shaven scalp. The temples and the nape of the neck are favourite areas for this purpose.

The country doctor to whom I was apprenticed in the good old-fashioned way certainly possessed a scarificator, the which is usually employed for wet cupping, but as certainly

he never used it to my knowledge. Now the scarificator seems to be unknown in France, and when wet cupping has been done the practitioner makes a few random incisions with a scalpel before cupping. This, of course, answers the same purpose, but it is a much more painful, because more tedious, operation than when the scarification is used. The only objections to the scarificator I can think of are the difficulty of keeping it strictly aseptic, with its multiplicity of inaccessible tiny blades and the difficulty of maintaining a good cutting edge on the blades. I find that it produces a very good impression on the *entourage* of the patient in cases in which wet cupping is indicated. "Click!" and there are twelve little rectilinear incisions ready to be sucked dry. Now that venesection has fallen into disrepute wet cupping affords a simple and safe way of abstracting blood. I have applied it with immediate and marked success in several cases of oedema of the lungs, and I succeeded in withdrawing quite a quantity of blood even when previous attempts at venesection had proved abortive, no blood issuing from the incised vein at the elbow.

I would venture to suggest to my fellow practitioners at home that recourse to cupping in suitable cases will benefit their patients. In pneumonia, in congestion of the lungs, in bronchitis, in pleurisy, in lumbago and sciatica, great and immediate relief can often be afforded. It is easy to apply:

A NATIVE PRACTITIONER CUPPING AN ARAB AT BOU-MEDFA, ALGIERS.

half a dozen thick rimmed kitchen tumblers—nothing can be better—a little cotton-wool or spirits of wine. If cotton be selected (the patient must be sitting up straight in bed) a loose tuft is placed at the bottom of the tumbler and when everything is ready a match is applied to it and the open end of the tumbler is sharply pressed into the chest wall. There is no fear of a burn if the patient be sitting straight up. It is important not to place the tumblers on loose tissue (such as the anterior abdominal wall), and they must not be placed too near to one another, otherwise they are apt, when the skin is drawn up, to pinch it very disagreeably. They are left on for five or ten minutes, and are removed by depressing the skin with the nail so as to let in air, whereupon the tumbler falls off. The skin is then dabbed dry and dusted with talc—never rubbed. When wet cupping is

contemplated the skin of the back must be thoroughly washed with soap and water, then rubbed with methylated spirit or a weak solution of iodine before applying the scarificator as well as after. Then the tumbler with the lighted cotton is placed over the scarified spot.

Some people use spirits instead of cotton, and as a matter of fact it gives better results, though it is attended by one or two risks against which one has to be on one's guard. A teaspoonful of spirit is poured into the tumbler and is swished round so as to moisten the sides. It is then poured out to the last drop, and a band an inch or so deep near the rim is wiped dry on the inside of the glass all round, so as to prevent the flame approaching the skin. The glass held in the right hand, is gently rotated so as to prevent the formation of drops, a match is applied, and it is quickly placed on the skin and firmly pressed. All danger of a burn is avoided (1) by having the patient seated bolt upright, (2) by keeping the tumbler rotating until ready to be applied, and (3) by having a towel handy to extinguish the flame in the event of a drop of lighted spirit falling on the sheet.

Algiers.

ALFRED S. GUBB, M.D.

PROFESSOR JULES BORDET, Director of the Pasteur Institute of Brussels, has been elected a foreign associate member of the Academy of Sciences of Paris.

A CONGRESS of French-speaking dermatologists and syphilologists will be held at Strasbourg from July 25th to 23th. The subjects to be discussed are: Desensitization in diseases of the skin, introduced by Ravaut of Paris and Spillmann of Nancy; Naevus-carcinoma, introduced by Masson of Strasbourg and Bloch of Basle; Treatment of the early stage of syphilis, introduced by Queyrat of Paris and Malvoz of Liège; Value of the various methods of administration of drugs in the treatment of syphilis.

SATURDAY, APRIL 14TH, 1923.

## PUBLIC HEALTH AND MEDICAL RESEARCH IN INDIA.

DELAY in making available here reports published in India is the rule, and the report of the Retrenchment Committee over which Lord Inchcape presided has not formed an exception. As was indicated last week (p. 609) abstracts in the Indian newspapers stated that while the chief reduction recommended was in the large military expenditure, the small sums allotted to public health and medical research were not to escape. The Finance Department of the Government of India has submitted to the Legislative Assembly a revised schedule of demands for grants for the expenditure of the Central Government, from which it would appear that the Government has agreed to the abolition of the posts of Director of Medical Research and of Public Health Commissioner, and also to the cessation of the annual grant to the Indian Research Fund. From a later statement by the Finance Minister, however, it seems that the Government has not yet made up its mind about the Public Health Commissionership. The abolition of the separate post of Director of Medical Research may possibly be a necessary economy; the proposal to transfer his duties to the Director of the Research Institute at Kasauli does not seem very happy, though it is proof that the Committee considered them to be of some importance. It is stated also that the Government is considering a recommendation of the Retrenchment Committee which aims at abolishing twelve bacteriological research appointments.

The annual grant to the Indian Research Fund was originally 5 lakhs (about £30,000); it was reduced during the war to 3½ lakhs, but the fund has accumulated a considerable sum of money, put at 33 lakhs (£200,000), to meet the cost of the erection and equipment of a Central Medical Research Institute at Delhi. Apparently the plans for this Institute are not to be proceeded with, and the Research Fund is to make use of the interest on the 33 lakhs to meet current expenses. The *Journal of the Indian Medical Research Fund* bears witness to the importance and variety of the researches carried out under its auspices and with funds supplied by it. It seems a paltry piece of economy to cut down the relatively small sum provided for the scientific study of the causes which lead to the high mortality among the 350 millions of the population of India. It represents an expenditure of about one-twelfth of a farthing a head a year.

Thus bad begins, and worse remains behind. The proposal to abolish the office of Public Health Commissioner for India (formerly called the Sanitary Commissioner with the Government of India) is a step backwards. All medical and sanitary subjects, including general provisions for public health, hospitals, dispensaries, research institutes, and sanatoriums, are among those transferred to provincial Governments, in pursuance of the policy, with which we have no quarrel, of making the Indian people self-governing. The Montagu-Chelmsford report said that the work of the European official in India may be expected gradually to undergo a change, so that "instead of continuing to the same degree as now as the executive agency of Government, he will stand aside more from

the work of carrying out orders and assume the position of a skilled consultant, a technical adviser, and an inspecting and reporting officer." But this has no bearing on the proposal to abolish the Public Health Commissionership.

In a statement lately put out by Colonel W. G. King, C.I.E., formerly sanitary commissioner with the Government of Madras, Sir Ronald Ross, K.C.B., and Professor W. J. Simpson, C.M.G., it is estimated that during the decade 1910-20 the death rate among the census population of 228 millions was in four years within a fraction of 30 per mille; in four other years it was considerably higher; in one year the rate, owing to influenza prevalence, rose to 62.4 per mille; the lowest rate recorded in any year was 28.72. These statements are based on the statistical abstract recently issued as a parliamentary paper. It is pointed out also that the mean expectation of life of the Indian male at birth, which was 24.59 in 1891, had decreased to 23.63 in 1901, and to 22.59 in 1911. In England the expectation of life of the male infant, which was 40.17 in 1841, had risen to 51.50 by 1910-12. The death rate of England and Wales last year was 12.9. There would seem, therefore, to be a good deal for the skilled consultant and technical adviser in public health to do in India.

The international aspect is also of very great importance. It must be remembered that though to officials, whether European or Indian, who are working in India the peninsula may seem to be a congeries of provinces and states, yet for the rest of the world India is a whole, a single country, with a rather evil reputation as a reservoir for great epidemic diseases such as cholera and plague. India is represented at official international sanitary conferences, and it is represented also in the Health Section of the League of Nations. How it is to make its voice heard, and how it is to deal effectively with the suggestions of other nations made at such conferences if it has no central public health department under skilled direction, it is difficult to see. In its letter to the India Office, published in the Supplement of April 7th (p. 103), the British Medical Association confessed its inability to understand the hesitation of the Government of India in giving effect to a progressive policy in health matters in India, and went on to point out that in this country it has been found politic recently to establish a Ministry of Health as an independent department of State with a Cabinet Minister at its head. That was written before the recommendation of the Inchcape Report to abolish the office of Public Health Commissioner in India was known. It is a criticism in anticipation of that recommendation, and it expresses, we believe, not only the medical but also the general public opinion in this country. However wise devolution in public health administration may be, the fact remains that from the international, as well as from many internal aspects of the matter, India must be regarded as one whole, and should therefore have an efficient central public health organization, responsible through the Governor-General and the Central Government of India, to the rest of the world.

## "THE NEW MIDWIFERY."

WE are glad to be able to print to-day an address by the late Dr. J. W. Ballantyne, delivered before the Nottingham Medico-Chirurgical Society at the beginning of this year and revised by him shortly before his death on January 23rd. The lecture will be read with interest as a concise and stimulating statement of "The New Midwifery," which has been evolved owing to the proved value of ante-natal hygiene, and the great success which has attended the treatment of the child during its mother's pregnancy. This success has been specially

marked in cases which, if not treated, would end in congenital syphilis, or in the less understood dangers incurred by the child in the presence of maternal toxæmias. Effective supervision of pregnant women, especially primigravidae, has saved both mothers and children from the dangers of obstructed labour in cases of contracted pelvis or other pelvic abnormalities, by a timely induction of premature labour, or by surgical interference at a prearranged date. Intelligent anticipation of obstetric complications has revolutionized midwifery by making it largely a preventive science, so that by preliminary measures the coming labour can be safeguarded and its risks avoided or minimized. Previous to the appreciation of ante natal hygiene, the obstetrician went to his midwifery cases prepared up to a certain point to prevent complications and to repair damages, but his efforts were practically concentrated within the time limits of the labour itself, whereas the management of the "new midwifery" goes back to the beginning of the pregnancy, or even to the preparation of the parents to become fit progenitors of their children. Dr. Ballantyne was practically the first to describe scientifically the diseases of the foetus. His book, published in 1892, was followed ten years later (1902-4) by his comprehensive *Manual of Ante-natal Pathology and Hygiene*. He has recorded his regret that this work was published just before the discovery of the spirochætal source of syphilitic infection (1905). The national importance and significance of his ante-natal observations were for many years not fully realized, especially as regards the loss to population from intrauterine disease and death.

In 1914, in an address on "Ante-natal Hygiene," published in the *BRITISH MEDICAL JOURNAL* of February 14th, 1914 (p. 355), Dr. Amand Routh collected estimates from various sources which seemed to indicate that as many fertilized ova perished *in utero* as infants died in their first year; the infantile death rate was then about 100 per 1,000 births. This estimate of the ratio of intrauterine to infantile deaths still holds the field, but cannot be scientifically established owing to the lack of organized statistics, especially as regards abortions. The loss of life in the war, which broke out six months later, emphasized the value of life even in its early stages, and ante-natal clinics are now at work throughout the country. Dr. Ballantyne did not cease to insist on this national aspect of foetal morbidity and mortality; he showed also that a large and unsuspected proportion of the foetal deaths occur during the actual birth, especially if the child be weakened by ante-natal disease or prematurity, or if there be a relatively contracted maternal pelvis. He gave the name "intra-natal" to this birth mortality, and this nomenclature has been universally adopted. It is estimated that its death rate probably represents about 25 per cent. of the total stillbirths. Dr. Ballantyne went farther and pointed out that a large percentage of the early post-natal deaths of children should really be included in this birth mortality because they are often due to preceding ante-natal conditions in mother and child. This explains the fact that in 1920, out of 76,552 infantile deaths, 9,894 (12 per cent) died in the first twenty-four hours of life, and 20,679 (27 per cent.) during the first week.

The value of Dr. Ballantyne's ante-natal researches has been enhanced by the conclusive demonstrations given in his wards and lecture room at the Royal Maternity Hospital, Edinburgh, where he had been able to reduce the stillbirth rate of his cases by 50 per cent. He proved that in order to render ante-natal clinics and pre-maternity wards fully effective they must be associated with a pathological laboratory for diagnostic purposes, and for research into the pathological chemistry of maternal toxæmias; he maintained also that

facilities should be provided for the treatment of venereal disease during the pregnancy. These aids he considered essential. He suggested, too, that a dental clinic should be available as a part of pre-maternity work, so that the mouths of all women likely to become mothers should be free from sepsis—a precaution which could be advantageously extended to the nurses, midwives, and doctors in attendance. These essential developments have been built upon the work begun by Dr. Ballantyne over thirty years ago, and it must have been a great source of happiness to him to have lived to see his views brought to full fruition. Many of those who have followed in his steps have been encouraged to do so by his personal advice and co-operation, by his numerous published addresses, and by the cordial private communications which his generous sympathy for the work of others impelled him to write. He realized that unless his medical colleagues endorsed his views and methods he could not, unaided, be successful in his aim and object—that every pregnant woman should arrive, at the hour of her labour, in a suitable environment, and with every recognizable risk removed, so that the obstetrician, when summoned to attend his patient, whether in hospital or private practice, would know that everything had been done to facilitate the passage of a healthy child through the normal pelvic canal of a healthy woman.

Dr. Ballantyne's address should be read by every practitioner and by every student, for it is only possible to ensure uncomplicated midwifery cases if everyone concerned in their management will accept his last message—truly a legacy of his life's work—and will carry out with care and intelligence the essential points in his recommendations.

#### JOHN VENN OF CAIUS.

ON April 4th passed away John Venn, Sc.D., F.R.S., F.S.A., who will be remembered by medical men as the biographer of Dr. John Keys and the historian of the college which bears his latinized name, Caius—more correctly *Gonville* and *Caius College*. The works which he wrote about the college are somewhat voluminous, and are characterized by thoroughness; but are for the most part full of human interest. As a rule they are pleasant reading, though in parts they are necessarily statistical. They include the following: *A Biographical History of Gonville and Caius College, 1319-1897*, a work in four large volumes, with portraits and other illustrations. *Gonville and Caius College*, an octavo volume in the Cambridge College Series. *John Caius*, a biographical sketch written in commemoration of the 400th anniversary of his birth, celebrated on October 6th, 1910. "The Annals of Gonville and Caius College," 1934. *Admissions to Gonville and Caius College, March, 1553-9, to January, 1603-9*. He wrote also several works dealing with the University in general, among which the following may be mentioned: *Early Collegiate Life*, containing sketches of life in the university in the olden times, with an appreciation of Dr. Caius, and the story of Thomas Dover, "The Buccaneer Physician," inventor of Dover's powder, and discoverer and rescuer of Alexander Selkirk on the island of Juan Fernandez. In addition he compiled, with the aid of his son, J. A. Venn, *Alumni Cantabrigienses*, a biographical list of all known students, graduates, and holders of office in the University of Cambridge from the earliest times to 1900 (the later volumes of which are yet to be published), and the Book of Matriculations and Degrees from 1544 to 1659; and with his wife he wrote Notes on the Persæ School, Cambridge, from 1619 to 1864, from the admission registers of *Gonville* and *Caius College* and other sources. The work of his early life was in the domain of logic, and he published three important books on that subject—namely, *The Logic of Chance* (1866), *Symbolic Logic* (1831), and *The Principles of Empirical or Inductive Logic* (1889), each of which went

through two or more editions. He also lectured on the subject, and was examiner for some years in the Moral Sciences Tripos; but he gradually laid it aside as his work in history developed. He took a prominent part in the work of the Cambridge Antiquarian Society, and was a frequent contributor to its publications. In his book, *Annals of a Clerical Family*, he records the history of the Venn family during some four centuries, tracing its origin to the Venns of Devon, who had probably migrated from Somerset. The name was at first spelt Fenn, but the spelling was changed to Venn to accord with the West Country pronunciation. John Venn was born in 1834 at Hull. He entered Caius College in 1853, and was Sixth Wrangler in the Mathematical Tripos of 1857. He was elected Fellow in the same year, subsequently became Senior Fellow, and was appointed President in 1903. He was in holy orders for some years, and in 1869 was Hulsean Lecturer, but he relinquished orders in middle life. Born of an evangelical stock, he was always an advocate of evangelical views. At his death, though in his 89th year, Dr. Venn retained to the full his clearness of mind and much of his activity of body. He was always willing to place his great store of knowledge at the disposal of others.

#### HOME MILK PRODUCTION.

THE Agricultural Tribunal of Investigation appointed towards the end of last year issued, on April 6th, an interim report which contains a section dealing with milk supply. At present nearly all the fresh milk we use is produced in this country, and the tribunal recommend that fresh milk and cream should only be allowed to be imported (under licence) when there is satisfactory evidence that the conditions of production and transport in the foreign country reach a hygienic standard equal to that required in this country. Imported dried milk should, it is recommended, be certified as free from adulteration, and on the tins of imported preserved liquid milk the constitution of the contents should be clearly stated. The committee has also considered the economic conditions under which fresh milk is produced in this country. There is, it is stated, evidence of a considerable increase in the number and extent of operations of farmers engaged in the production and supply of fresh milk. As a result there tends to be a recurring crisis, due to over-production of milk, particularly in summer, and resulting in considerable loss through wastage or uneconomic use of milk. The remedy for this lies in the erection by associations of farmers, or by companies who purchase their milk, of milk-collecting dépôts at local centres, equipped with plant for the proper treatment of the milk before raling and for the conversion of the surplus milk into dried or preserved milk, butter, or cheese. The economic value of such societies is great, for they assist payments according to quality, economy in collection, and treatment of surplus milk, while the by-products can be used locally for feeding stock. Foreign and colonial experience has fully demonstrated the advantages of such dépôts equipped for converting surplus milk. Dépôts in Scotland have been of much benefit to dairy farmers, and the same is or was true of the creameries in Ireland. The Tribunal expresses the opinion that the State should actively encourage the formation of such societies or companies—advancing loans to assist in the erection of the necessary plant, as has been done in Scotland. Further, in the interests both of the farmers and of the food of the community, an active propaganda should be carried on to increase the consumption of milk, as has been done with most marked success in recent years in the United States.

#### THE EFFECT OF TROPICAL CLIMATE ON EFFICIENCY.

At a meeting of the War Section of the Royal Society of Medicine on April 9th, Squadron-Leader T. F. Rippon, R.A.F., discussed the effect of tropical life upon physical and mental vitality. A good deal of the paper was occupied with a description of his investigations on eye trouble due to

tropical glare. Such trouble might manifest itself, he said, as a superficial irritation, with certain slight symptoms including frontal headache, or as retinal fatigue, with dimness of vision at night and prolonged after-images, or as an inability to sustain accommodative and convergent efforts for any length of time. He had examined certain flying men in Egypt who showed signs of this last defect. Every exciting cause other than glare was excluded, and an attempt was made to measure the impairment of accommodation. It was possible only to represent the results roughly, but he found in a certain group of men who had complained of eye fatigue that their power of accommodation was only about half what it should have been. The disability was more noticeable in the months of May and June than in April. This inability to sustain accommodation caused discomfort, but in its mild form it did not interfere with the estimation of distance on landing an aeroplane. Only when there was marked failure of accommodation and convergence for near points was the judgement disturbed; but, of course, a degree of fatigue which might cause no error of judgement in an able and experienced pilot might so result in a novice. Even the seasoned pilot, however, when his eyes showed signs of wear and tear on account of tropical glare, would admit that he no longer made his landings automatically as he used to do, but had to take conscious care and deliberation, and was often filled with apprehension. Thus he tended to lose self-confidence and the visual disorder became, in its turn, the cause of psychological trouble. From this it appeared that the receding of near-point accommodation was the sentinel symptom of eye fatigue, calling for further examinations. The association between tropical glare and the breakdown of convergence was studied also. Optometric measurements showed poor convergence—the near-point of convergence being outside 4 in.—in eight out of a group of thirteen cases suffering from effects of glare, and here again the condition was worse in May and June than it had been in April. The speaker then discussed the influence of a tropical climate in developing a psychoneurosis. Besides the fatigue caused by heat and glare, and the irritation from insect bites, there were other tropical conditions, such as lack of nourishing food and periodic attacks of gastric disorder, which were likely to impair the higher centres' control over the lower. Thus the resident in the tropics might be unable to concentrate, or might give way to anger over trifles. An intelligent adaptation to environment would discount these effects in time; nevertheless, before this adaptation was learnt there might be sufficient loss of control to produce a psychoneurosis. Other predisposing factors in tropical life included the sense of being always under critical observation, an exaggerated desire to maintain prestige, and the strain of keeping watch over emotions, associated perhaps with racial antipathies. The European in India, where the Mutiny was still remembered, could not forget that he was living in the midst of a potentially hostile race, and it was this which accounted probably for the habit of Englishmen in India at every station to congregate in clubs. To these conditions, in the case of men in the Air Service, was added the emotional stress of an occupation which was a new adaptation of the human organism, was taken up by the individual in adult life without previous education, and was associated with danger on every occasion. In the course of a brief discussion Major J. W. Spencer suggested that neurasthenia might explain many of the mental or nervous symptoms seen among men on tropical service. The neurasthenic was under the sway of an emotion of which he could not get rid by the exercise of his free will, and which paralysed or undermined his judgement; he showed also a loss of power of concentration and a general lack of mental energy, or an inability to pull himself together. The man who had been in the tropics for a number of years, although he returned home vigorous enough in general health, often complained of some impairment of memory and a difficulty in taking up close work, such as study for an examination, which might be required of him; also he inclined to pessimism. These were the symptoms of the neurasthenic. The great saving thing in the trouble was

to have some interest outside oneself which would serve as a way of escape. It might take the form of religion, family devotion, or genuine interest in work or sport. Service abroad took a man away from all his former associations and subjected him to the strain of a hot climate and to other strains, but the worst thing it did was to leave him with considerable unoccupied spaces of time. Such conditions gradually led to a habit of introspection, which was the beginning of the neurasthenic state. The remainder of the discussion consisted of a few remarks by several speakers on the irritability often shown by the tropical resident. There was a disposition to accept a physiogenic rather than a psychogenic explanation, and the general idea appeared to be that it was due to congestion of the liver. Squadron-Leader Rippon agreed that the liver might have much to answer for, but he still held to the view that the primary cause was a loss of psychic tone, resulting in a diminished control by the higher centres over the lower.

#### HARVEY AS AN ART CRITIC.

AN interesting paper on Dr. William Harvey as a man and an art connoisseur was read by Sir D'Arcy Power at the Paris Congress of the History of Medicine in 1921, and has now been published in its *Transactions*. For the most part Harvey's biographers have concentrated upon his scientific attainments, and few have thought of him as a man of like parts and passions as ourselves. Sir D'Arcy Power deals with his human side—with his hobbies and his earlier years. The early Stuart period was marked by a renaissance of art in England. Even in the later years of Elizabeth's reign art collectors existed, chief among them being the Lord Lumley, founder of the Lumleian lectures at which Harvey was destined to announce his discovery of the circulation of the blood. The fashion spread rapidly under James I. Within ten years of his accession the Earl of Arundel, the Earl of Essex, the Duke of Buckingham, and Lord Pembroke were buying art treasures in Italy, in Spain, and in the Levant; were commissioning artists like Rubens and Van Dyck; and were employing such agents as Inigo Jones and the Rev. William Petty to advise and help them. Whilst Inigo Jones was studying painting and architecture in Italy at the expense of Lord Pembroke, Harvey was studying medicine at Padua, where he graduated in 1602. Later in life they certainly were acquainted, for in 1655, three years after the death of Jones, John Webb published *Stonehenge Restored* at the instigation of Harvey and Selden, a work which Jones had left unfinished. Apparently Harvey's residence in Italy had engendered in him a love of the arts, especially painting. The number of portraits for which he sat suggests that he was an unusually good sitter, who was thrown much into the company of artists. In 1636 Harvey travelled in the suite of the Earl of Arundel when that nobleman was sent as Ambassador Extraordinary to the Emperor Ferdinand II. In the course of this tour Harvey was given "a little start" into Italy with "some employment to Mr. Petty about some pictures for His Majesty." The Rev. William Petty was one of Lord Arundel's agents and art collectors, and it is to his artistic acumen that we are mainly indebted for the Arundel marbles. Harvey's journey from Ratisbon to Venice was not without adventure. On the pretence of an irregularity in his passport he was detained at Treviso, whence he wrote angry letters of complaint to Lord Feilding. Lord Arundel heard of his difficulties and wrote to Mr. Petty: "I hope poor Dr. Harvey is with you by this. I received a letter from him yesterday that he has been miserably vexed in the lazaretto at Treviso. I hope he will recover his time lost with satisfying his curiosity, which you will assist him in at Florence and Rome." Of Harvey's energy the Earl speaks jestingly in another letter to Petty: "I hope I shall see the little perpetual movement called Dr. Harvey here before my going." These letters show throughout that Harvey was held in high estimation for his personal qualities, and that so great a judge of men and art as the Earl of Arundel thought him

worthily to be entrusted with a commission to buy art treasures at Rome for the King. It is true that the Earl considered Harvey only as an amateur and entrusted him to the care of Petty, who was a professional in the art of collecting. But the correspondence bears out what we knew from other sources—that Harvey in his prime was a genial and lovable little man with artistic taste that ran in the direction of pictures. It is perhaps not without importance to reflect that other great scientific discoverers, notably John Hunter, Jenner, Sir Charles Bell, Charcot, and Pasteur were, like Harvey, men of uncommon artistic tastes.

#### SMALL-POX PREVALENCE.

THE Registrar-General's returns show that 213 cases of small-pox were notified in England and Wales outside of London in the five weeks ending March 31st, the latest date to which the official returns are at present available. In the successive weeks the numbers were 45, 53, 35, 28, and 52. The counties affected were Derby with 67 cases, the West Riding of Yorkshire 41, the North Riding 23, Lancashire 42, Nottingham 20, Durham 7, Gloucestershire 8, Stafford 4, and Lincolnshire (the Lindsey) 1 case. In Derbyshire Clowne had 31 cases and Heanor 26, in the West Riding Doncaster had 24 cases and Adwick-le-Street 8, in the North Riding Middlesbrough had 22 cases, in Lancashire Nelson had 40, the county borough of Nottingham had 6, in Gloucestershire Cheltenham had 5, and the county borough 3. From local newspapers we learn how the disease continues to manifest itself in places already attacked, as in Clowne and Stapleford and Nelson. At Clowne it seems a prominent local anti-vaccinationist was summoned to the police court for failing to notify a case in his house, but he was unable to obey the summons, as in the meantime he himself had been attacked by the disease and removed to hospital. At Nelson, where it is said there are many anti-vaccinationists, special efforts were being made to control the infection. Day schools and Sunday schools were being closed, children were being excluded from cinemas, many proposed entertainments and meetings had been postponed, a political club bazaar had been deferred to November, various other arrangements cancelled, and the existing hospital accommodation has been largely extended. At Hebden Bridge a Bradford woman on a visit to friends felt ill and went to the consulting-room of a local doctor, where, after being seated in a waiting-room with fifteen other persons, the doctor found she was suffering from small-pox; he had her removed to hospital whilst he vaccinated all the people in the surgery and the contacts as far as discovered. His prompt action is much to be commended. At West Bromwich a case was notified on March 27th and isolated in hospital, all known contacts being vaccinated. In our issue of March 10th it was stated that in the first eight weeks of the year 305 cases had been reported outside of London. The 213 notifications in the succeeding five weeks bring up the total to 518 for the quarter, and the disease, as just indicated, continues to be heard of from various localities. Fortunately London remains so far free from the infection since the suppression of the outbreak in Poplar workhouse. From Geneva intimation has been received of epidemic small-pox in mild form in various parts of Switzerland.

#### ENVIRONMENT AND INTELLIGENCE.

THE Medical Research Council has issued a report<sup>1</sup> of a piece of work, originally undertaken by Mrs. Frances Ward, and on her death arranged for publication by Dr. L. Isserlis, on the relation between home conditions and the intelligence of school children. The material analysed was collected mainly in two London schools in similar neighbourhoods and near together. The social conditions of the children were ascertained by reference to the medical record cards. The teachers furnished estimates of the intelligence of the children, and, further, a psychological test was made by the investigator.

<sup>1</sup> Stationery Office, 1923. pp. 23. price 1s. net.

The correlations of the marks obtained in the intelligence tests with age and the teacher's estimate of intelligence were sufficiently high to warrant confidence in the teacher's work. In the lower classes the younger children and in the upper classes (to a slight extent) the older children were considered by these teachers to be more intelligent. This was possibly explained by the presence of mentally defective children in the lower classes who would have been removed to special schools before upper classes were reached. The correlations between the teacher's estimate of intelligence and social position were all positive—that is, the children of higher social position showed more intelligence. The more intelligent girls were better clothed. It is considered that on the present data it is justifiable to conclude "that progressive improvement in home conditions may be expected to react favourably not only on the health but also on the intelligence of school children. Another argument, if additional arguments are needed, is thus provided for further efforts to ameliorate the home conditions of the children who attend elementary schools." It is, however, admitted that this conclusion is open to argument, for it may be that the better clothed and cared for children who show superior intelligence are better cared for because their parents are of superior intelligence and industry and the superior parents hand on their superiority to their children. The research is of much interest, and it is to be hoped that it will be extended so as to throw some real light on the shares of environmental and inborn factors in producing intelligence.

#### RACIAL ASPECTS OF ALCOHOLISM.

An address, designed to introduce discussion on the differences in the distribution of alcoholism in different races, was delivered by Dr. W. M. Feldman before the Society for the Study of Inebriety on April 10th. Unfortunately, perhaps because the subject was too complex, little or no discussion was forthcoming. The fact that there was a differential incidence of alcoholism among the various races was accepted by Dr. Feldman as unquestioned. The sobriety of the Jew was, he said, proverbial, and was borne out by his own professional experience. In the course of some twenty years' practice among Jews of all classes he had come across not more than two or three cases of alcoholism. His patients included a number of Jews who were engaged in the sale of alcoholic drinks, but they were nevertheless perfectly sober. He also quoted some statistics of the American Army in 1917-19, showing the percentages of alcoholism found among the men of fifteen different races. The Mexicans were at the bottom of the list, and the Irish at the top. The percentage among African negroes, Jews, and Italians, was very small. The question was whether these wide differences in the frequency of alcoholism were truly racial in character or due to circumstances connected with environment. Was it to be believed that there was a correlation between the inborn physical or psychological characters of a race and its tendency towards or away from alcoholism, or must the differences in sobriety be assigned to such external factors as climate, social control, and economic conditions? The answer called for the patient co-operation of unbiased experts in several fields. It had been suggested that there was some peculiarity in the composition of the blood of the different races which altered the nervous stability so that some races fell an easier prey to alcoholic indulgence than others. This theory was no more than a vague belief; the evidence seemed to be against it, for if the craving for alcohol was determined by the blood, it was to be expected that particular hormone in the blood connected with the craving the same constituent would be as or narcotics, but statistics for other kinds of stimulant failed to reveal any positive correlation between alcoholism and other drug addiction. In some detail with sober in all climates. Dr. Feldman dealt with the theory advanced by Sir Archdall Reid that the craving for alcohol is a hereditary character

parent to offspring, and that the drug has tended in the course of generations to weed out its addicts. It was urged by the supporters of this theory that the modern Jew was temperate because the ancient Hebrews drank to excess. Dr. Feldman denied that alcoholism was excessively prevalent among the ancient Hebrews. Nor was it the fact that Jews drank less than Gentiles. Jews drank considerable amounts of alcohol but they did not get drunk, probably because they seldom drank alcohol without at the same time taking food with it, and because there were social prohibitions among Jews which prevented intoxication. On the theory of selective action environment should have no effect upon the incidence of alcoholism, but the statistics of the American Army showed that the tendency amongst the native-born of the various races was to approach the mean for alcoholism for the whole of the United States, so that offspring of parents amongst whom the percentage of alcoholism had been high had a lower incidence of alcoholism, and the converse, almost in accordance with Galton's law of filial repression. According to the selective theory, alcoholism could only be cured by the extermination of the drinker, not of the drink. Elaborate and extensive eugenic measures might ultimately eliminate alcoholism, but the remedy might be worse than the disease. Moreover, biological evidence tended to show that it was not the actual but only the potential personality which was predetermined in the germ cells. In a brief discussion Dr. C. F. Harford said that he could not believe that racial susceptibility to alcohol was something in the blood or something handed down in the germ plasm. He believed that it was determined by the habits of races. The restraining or provocative influences were social customs, religious observance, the existence of facilities for drinking, and the economic situation.

#### CLUBBED FINGERS IN SUBACUTE INFECTIVE ENDOCARDITIS.

The physical sign of clubbing of the ends of the fingers, sometimes called Hippocratic fingers, though the Father of Medicine referred rather to overcurving of the nails, has been the subject of many short studies, and its causation has excited no little interest. Its association with cyanosis and local venous stasis of cardiac origin on the one hand, and with infective conditions, especially in connexion with the lungs, such as bronchiectasis and empyema, has long been recognized; but it is rather remarkable that infective endocarditis has only recently been realized as a frequent and important causal factor. This may be due to the increased incidence of subacute bacterial endocarditis as a result of war conditions and especially to the opportunity thus provided for their intensive study in the Sobraon Military Heart Hospital at Colchester. The history of this clinical observation and the results of a collective investigation into this subject carried on at University College Hospital between September, 1919, and March, 1921, have recently been given by Dr. Thomas F. Cotton.<sup>1</sup> Soon after the Colchester Hospital was opened in 1917 the association between clubbed fingers and subacute infective endocarditis was thought to be more than a coincidence, and before the hospital closed this sign was regarded as one of the most reliable guides to the diagnosis of this cardiac lesion. Attention was called to this in 1920 in our columns by Sir Thomas Lewis and by Dr. Cotton (BRITISH MEDICAL JOURNAL, 1920, ii, 301, 851), and Dr. Cotton has now expanded his observations and given an elaborate analysis with several tables dealing with 63 examples of clubbed fingers among 798 cases of acquired cardiac disease in army pensioners. Statistically clubbing of the finger-tips was found to be specially associated with chronic venous congestion and aortic regurgitation; but this relationship was not direct or exclusive and is explained by the almost constant presence of venous stasis in subacute infective endocarditis, the predominant lesion of which is aortic incompetence. Out of the 63 cases with clubbed fingers no fewer than 41, or 70 per cent., undoubtedly were examples of infective endo-

<sup>1</sup> T. F. Cotton: *Heart*, London, 1921, ix, 317-321.

carditis and proved fatal within a year; 4 more presented doubtful signs of infection. In the remaining 15 cases, 5 of which proved fatal, the clubbing of the fingers appears to have been unconnected with the cardiac disease; in 2 instances it had existed for many years, and in some of the others it consisted in thickening of the nail bed associated with small breaks in the skin of the lunule of the nail; the chronic superficial irritation thus excited probably caused the clubbing, which is not uncommon in the damaged fingers of labourers.\*

#### STATISTICS OF A BABY CLINIC.

THE latest publication of the Department of Applied Statistics at University College is a *Study of the Data Provided by a Baby Clinic in a Large Manufacturing Town*, by Miss Mary Noel Karn and Professor Karl Pearson.<sup>1</sup> The general problem the authors attempted to solve was: "What factors are there in heredity or environment which influence the general health of our babies?" The material appears to them "neither superlatively good nor, on the other hand, superlatively bad. It is just what you might anticipate it would be, after the first enthusiasm of promotion has died down when a big scheme is carried out largely by voluntary and only partially trained 'field workers' who lack the intense earnestness of real scientific minds. Yet on the whole the results are in good accordance with the more weighty material we hope shortly to publish on infant welfare as investigated under the control of the local medical officers." Information was supplied respecting rather more than 1,700 infants, and the data have been analysed by the method of correlation, but salient features are, for the benefit of the non-statistical reader, exhibited in diagrammatic form. The general conclusions are set out under thirty-three headings, and may perhaps be indicated by saying that no factor evaluated could be deemed of paramount importance in the determination of infant welfare. A large majority of the coefficients of correlation were small, many not significant having regard to their "probable errors." In some instances where a correlation was large, its *prima facie* interpretation was suspect. A good example is the use of a baby "pacifier" or "comforter." Most medical men, perhaps most people who attach importance to cleanliness, have stigmatized these dirt-accumulating instruments. Considering the data as a whole, there were 769 records of the use of a comforter, 496 where it was not used. Taking the record of experience down to the end of the first year, 75 per cent. of the comforterless infants are in good health, and only 2.4 per cent. dead; 60.3 per cent. of the users of comforters are in good health, 13.9 per cent. dead. Expressed in the scale of correlation, the correlation between use of comforter and health is  $-0.2501 \pm 0.0298$ . This looks very bad for the comforter, but if the relation between a baby's health during the first fourteen days of life and the use or non use of the comforter during the whole year be scrutinized, it is found to be much larger—namely,  $-0.47 \pm 0.08$ , while again the mother's health is appreciably ( $-0.1662 \pm 0.0298$ ) correlated with the use of the comforter. "Thus," write the authors, "as far as the present statistics are concerned, we have not been able to trace any marked influence of the comforter. Whatever influence it may have is screened by the selection of the babies on the one hand and the mothers on the other who adopt it." The criticism which will be passed upon the data as a whole—that is, that the smallness of the various correlations is a consequence of the dilution of the material by errors of observation, careless or inaccurate recording, etc., a criticism which is only of value when more exact particulars leading to other conclusions have been assembled—cannot explain away this difference. We do not suppose that the most pessimistic reader of Miss Karn and Professor Pearson's memoir will be convinced by it that infant welfare work is waste of money and energy. We do not think that Miss Karn and Professor

Pearson desire to create that conviction. The lesson which is inculcated is that, in the matter of infant welfare, as in every other problem of preventive medicine, truth is hard to come by; one must travel by a long, difficult, and weary road. The correlational method of locomotion is not particularly exhilarating, but its devotees are entitled to cite Horace:

Vive; vale. Si quid novisti rectius istis,  
Candidus imperti: si non, his utere mecum.

#### SCHOOLS FOR MENTALLY AND PHYSICALLY DEFECTIVE CHILDREN.

THE Board of Education has issued a circular<sup>1</sup> on the arrangements of the "special schools" for defective children. The Board desires that all those children who need special educational methods should have this advantage, but that it should be provided at the least possible cost. To that end it has decided to adopt a less costly standard of staffing. At present teachers for these schools must possess certain specific qualifications. It is now proposed "to recognize as a teacher a person who does not possess those qualifications, provided that they are satisfied by inspection that he or she is competent to do the work, and that the staff of the school as a whole is adequate and suitable." Further, the teachers are to work harder. The numbers of the children in each type of school are to be increased: in the schools for the blind from 15 to 20; in the schools for partly blind from 20 to 25; in some schools for the deaf from 10 to 15; in those for mentally defectives from 20 to 25 in the junior classes; in those known as open-air schools from 25 to 40; and in the schools for cripples from 20 and 25 to 30. The question arises: Will the teachers be able to cope with this increase of work? These "classes" are not classes in any real sense of the word; the children in them are not fairly homogeneous groups of similar age and capacity who can be taught as a whole. The variety of age and disability makes individual teaching the rule rather than the exception, and it would seem that the additions of, roughly, 25 per cent. to the numbers each teacher has to teach will make the task so difficult that it will fail to be done. The proposed economy may in the end prove a serious waste of money and energy. The difficulty will be increased if untrained teachers are accepted as is provided in the circular; and it may be noted that no indication is given therein of what the Board considers fitness for this difficult work in the absence of any recognized qualification. Will the Board interview each candidate for a teachership, from whatever part of the country he or she may hail? A further circular letter issued by the Board of Education<sup>2</sup> deals with the payments by a local education authority for the education of children who are blind, deaf, or otherwise defective, in a school maintained by another authority or voluntary managers. Hitherto the Board has required that each such arrangement should be submitted to it for its approval, together with a statement of the payments to be made. Now it proposes, as a means of reducing clerical and administrative work, that the local authority should only be required to submit for approval a single application in general terms for the payment by the authority to any and every special school duly certified under the Act of 1921 to which the authority may wish to send children at fees that are current and approved.

#### AN ANCIENT EGYPTIAN MEDICAL PAPYRUS.

It is announced in a preliminary number of the Oriental Institute Communications of the University of Chicago that the New York Historical Society has entrusted Mr. J. H. Breasted, director of the Oriental Institute of the University of Chicago, with the preparation for publication of a medical papyrus acquired by the Society in 1936. The papyrus is believed to be of the end of the seventeenth century B.C., but may be as late as 1600 B.C. It is a roll over 15 feet in length, with columns 11 or 12 inches high. The important part of it

<sup>1</sup> Drapers' Company Research Memoirs—Studies in National Deterioration, X, pp. 128, with 48 diagrams and two charts. Cambridge: at the University Press. 1922. Price 15s.

<sup>1</sup> Board of Education Circular 1297, January 29th, 1923, to local education authorities and to managers of special schools.

<sup>2</sup> Circular 1298, February 9th, 1923.

is contained in seventeen columns in the front of the roll, in which there is a portion of an ancient treatise on surgery and external medicine. Unfortunately the beginning, which dealt with the head, is lost, and the scribe did not continue his copy farther down than the thorax and the beginning of the spine. The document differs strikingly from all the other known Egyptian medical books in that it is not a list of recipes or prescriptions, but an orderly arrangement of cases carefully observed. It contains a series of forty-eight, each recorded in the following order: Title, always beginning, "Instructions for . . ." (name of ailment); examination, always beginning, "If you examine a man having . . ." (symptoms follow); diagnosis, always beginning, "You should say concerning him: 'A sufferer with . . .'" (name of trouble follows); verdict, which is always one of three, "An ailment I will treat" (favourable), or "An ailment I will contend with" (doubtful), or "An ailment I will not treat" (unfavourable); treatment; explanatory glosses. This systematically arranged material, especially in the examinations and the explanatory glosses, reveals a scientific attitude which approaches the modern standard. The cases are in the main examples of various forms of injury, such as a sword-cut in the skull, and as these are due to physical causes quite clear to a physician they can obviously, even to the Egyptian mind, have no connexion with the activities of malignant demons of disease. The document is therefore not influenced, as other Egyptian medical documents are, by demoniacal medicine, and the mind of the ancient Egyptian is revealed as interested in the observable facts of science for their own sake. Mr. Breasted hopes to have his translation and discussion, with a facsimile reproduction of the hieratic text, ready for publication towards the end of the year; it will be issued by the New York Historical Society. —

and abet counsel or procure the commission in any place outside Great Britain of any offence punishable under the provisions of any corresponding law in force in that place," or to do "any act preparatory to or in furtherance of any act which if committed in Great Britain would constitute an offence against this Act." This seemed to him to place British law at the disposal of any other country which at any time might pass an enactment making, say, alcohol a dangerous drug. That was, perhaps, a farcical illustration, but let them take, for instance, laws which might be passed in Turkey, China, Japan, or the United States. He did not know whether there was any precedent for enacting in advance such severe penalties for aiding, abetting, and counselling the commission of any offence punishable under the provisions of any corresponding law in some other country. It seemed to be opening a very wide door.

Sir Sydney Russell-Wells said he would like to compliment Mr. Webb on the interest he had shown in medicine, but could not compliment him on being up to date. If he had followed the bill as amended in Committee most of his speech would not have been made. The distinction originally drawn between the medical man in actual practice and the other medical men had now disappeared. Moreover, if Mr. Webb had looked up the Acts to which reference had been made in the bill, he would have found that the schedules had been revised several times since they were first drawn up. Sir S. Russell-Wells, on behalf of the medical members of the House, expressed great appreciation of the courtesy and consideration shown by the Home Secretary to their representations. He had adopted in spirit every suggestion put before him. He had recognized that they were anxious to help him in making a bill which would remove abuses. It was impossible to say that all points had been provided for. It was almost certain that in actual practice small difficulties would arise, but he was sure that under the present administration they would be removed so far as possible by administrative Order. He thanked the Home Secretary for removing the Regulation which prevented doctors prescribing for themselves.

Mr. Bridgeman said that Sir Sydney Russell-Wells had really answered the questions put by Mr. Webb. What had happened in Committee was that the words "in actual practice" had been omitted from the bill, and thus the difficulty which Mr. Webb had mentioned had gone. If the House allowed the Regulation (revoking the prohibition against self-prescribing), then the words complained of would be entirely removed both from the bill and the Regulation. The schedule to the Amending Bill was made up under Section 2 of the original Pharmacy Act of 1868, and it had been brought up to date to 1908. Under Section 2 of that Act it was possible, on the advice of the Pharmaceutical Society Council, to add to the schedule. If they could convince the Home Office that any other drugs ought to be added, these could be added under Order in Council. With regard to corresponding laws in other countries, Mr. Bridgeman referred Mr. Webb to Subsection (2) of Clause 6, which explained the corresponding law very fully. It read:

"Any law stated in a certificate purporting to be issued by or on behalf of the Government of any country outside Great Britain to be a law providing for the control and regulation in that country of the manufacture, sale, use, export and import of drugs in accordance with the provisions of the International Opium Convention signed at the Hague on the twenty-third day of January, 1912."

That should provide sufficient safeguard to meet any apprehension.

Dr. F. E. Fremantle referred to two points of particular interest. One was the reduction of penalties for minor offences under the bill. There were now two series of penalties for two series of offences. As the bill originally stood a medical man who, through carelessness or through the fatigue of a day's work, might have failed to enter particulars in a book or to keep some records, would be subject to the highest penalty. It was desirable to have that matter corrected. The other point was contained in Subsection 2 of Clause 4. Under the clause every bottle containing medicine which included any of these poisons was to be labelled with the name of the poison and with particulars as to the proportion of the poison to the preparation. That met a difficulty in reference to patent medicines. The medical profession and the chemists always insisted in the public interest that it was essential that patent medicines, in view of the protection which they had from the law, should be bound to show their ingredients. On the other hand, those who stood for patent medicines and the commerce which they represented held that such a course was not in the interests of British trade, and that it involved revealing trade secrets. This bill met the conflicting claims. The pill maker or the patent medicine maker might still put all sorts of confections and infusions into his medicine—all the frogs' livers, the flowers, the herbs, and various other things—without revealing the secrets, but he was bound to give the proportion of any dangerous drug in the mixture. That formed a remarkable instance of sound legislation meeting two opposing views in the public interest. He joined in thanking the Home Secretary for his action in amending the bill.

Dr. Chapple recalled the report of the Patent Medicines Committee, which showed that one of the greatest evils spreading throughout this country was that of the traffic in secret remedies with which this bill did not deal. He appealed to the Government to take a long step farther and introduce legislation to remedy the evils which were there brought out. The report came at a very unfortunate time, being issued in July, 1914. It actually called attention to the vested interests which were supporting the patent medicines traffic, and therein lay a difficulty in legislation but he hoped that the Government would take the matter up.

Mr. Russell-Wells was read a third time.

# NINETY-FIRST ANNUAL MEETING of the British Medical Association, PORTSMOUTH, 1923.

## OLD AND NEW HOSPITALS IN PORTSMOUTH AND NEIGHBOURHOOD.

The origins of our hospitals are wrapped in the mists of the past. Even before the time of Tutankhamen sick and ailing Egyptians were taken to the temples that they might sleep in the mystic shadows of the pillars in the hope that the gods would in their kindness make whole the sick.

When and by whom the first hospital in this country was founded it would be difficult to state. One of the results of the revival of religion which followed the Norman settlement was the establishment of houses for the relief of the sick, the poor, and the infirm. Probably the earliest distinct record of the building of a hospital in England is that recorded in the life of Lanfranc, Archbishop of Canterbury. It is therein stated that in 1080 he founded two hospitals—one for the cure of leprosy and one for the cure of ordinary illnesses. These early charitable establishments remained in the hands of the religious houses till the time of the Reformation. St. Bartholomew's in London is about the oldest of these pious foundations, having been established in 1123. A few years later St. Thomas's was opened. These two, with Bethlehem, Bridewell, and Christ's Hospital, were for a long time known as the five Royal Hospitals.

### ANCIENT HOSPITALS OF HAMPSHIRE.

In the county of Hants we have one of the best examples of these mediæval hospitals that has come down to us. Bishop Henry du Blois—younger brother of Stephen—built his Hospital of St. Cross in the meadows south of Winchester. In 1136 he gave to it a statute placing it under the care of the knights of St. John of Jerusalem, but the charter was not confirmed till sixteen years later. Early in the thirteenth century control of the hospital was finally surrendered by the knights to the Bishop of Winchester, after considerable controversy between the knights and Henry II. Subsequently Cardinal Beaufort grafted on to the ancient foundation of Henry du Blois his "Hospital of Noble Piety." Having endured many vicissitudes and abuses the hospital fell into desuetude, but in 1831 the old foundation was revived, and the brethren of St. Cross are again in residence, and the daily dole to travellers is again dispensed. In connexion with this foundation it may be interesting to note that Henry du Blois gave command that thirteen of the poorest scholars of St. Swithun's School should each have his meals daily from St. Cross. St. Swithun's was in those days an old scholastic foundation that gave free education. Here, then, early in the thirteenth century, was already carried out in practice the present-day demand of free education and free meals for necessitous children.

As St. Cross was the great hospital for Winchester, so that of St. Julian functioned in like manner for Southampton. The old Maison Dieu was founded by Gervase le Rich, a wealthy merchant of Huguenot extraction, a Burgess of Southampton towards the end of the twelfth century. It was dedicated to St. Julian, the patron saint of travellers and those in want of hospitality. It was intended probably for the special use of pilgrims who were wending their way to Canterbury, a fashion that was then coming into vogue. The road to Winchester runs over the site of the old hospital.

Other ancient hospitals in Hants were those of St. John the Baptist at Basingstoke, founded by Walter de Merton in 1261; and one similarly dedicated at Andover, reputed to have been established by the Conqueror. In addition to these general hospitals others were especially established for lepers on Magdalen Hill, Winchester; at Southampton, Christchurch, and Newport.

### *Hospital of St. Nicholas, Portsmouth.*

The Hospital of St. Nicholas, better known as the "Domus Dei," was founded by Petro de Roche. Bishop of Winchester

between 1236 and 1212. It was the oldest foundation of its kind in Portsmouth. It was dedicated to St. Nicholas, a saint whose special function was to look after sailors and those in peril on the seas. The long main building consisted of a chapel at the east end, a large central part used as the hospital, with a wide porch at the west end. In addition to the large building there was a gatehouse, a guesthouse, and a Master's house, a large kitchen, larder, bakehouse, and stables. It was governed by a Master and Brethren, and derived some of its income from ground in St. Mary's Street given by King John, and from a portion of the manor of Fratton given by the burgesses of Portsmouth. It did good work for many years, but there were occasional complaints. One, for example, in the fifteenth century that "the pour pepull has nott ther bred baked and ther drynke brewed in the howsse as yt was wont for to be, and the Master kepeth there no ospitalite wiche ys a gret decay to the toune." The hospital was closed by Henry VIII in 1540, and subsequently the building was used as a munition store. The fabric was neglected and became ruinous, but in 1581 the church was repaired and the other buildings converted into the official residence of the Military Governor of Portsmouth and continued as such for three hundred years. In 1826 the Governor's House was demolished, but the dilapidated chapel was allowed to remain. Its restoration was begun in 1866, and it is now used as the garrison church.

The hospital for lepers was a little way outside the old town wall, on the site now occupied by the Guardians' offices. The hospital was dedicated to St. Mary Magdalene and St. Anthony. Mr. Gates says there is some evidence of another ancient hospital in the old borough. It was connected with the Chapel of Our Lady of Close, which stood on land now covered by Colewort Barracks, and appears to have been founded by a social and religious guild. On this old site the first military hospital in Portsmouth was erected, and that probably was the first in the kingdom.

### MODERN HOSPITALS.

The Hants County Hospital, Winchester, was founded in 1736 by Dr. Alured Clark, a Prebendary of Winchester (afterwards Dean of Exeter), in imitation of St. George's Hospital, London. This was the first attempt to found a hospital of this kind in this country outside of London and Westminster.

The hospital movement commenced in Portsmouth just a hundred years ago. The Portsmouth Public Dispensary was opened in St. George's Square in March, 1823. The work at first was partial and spasmodic. In 1836 Dr. Engleue started a campaign for establishing a general hospital. He submitted a plan to the committee of the dispensary which, together with the introduction of beds in some of the rooms, would make the institution suitable for the reception and treatment of patients. Considerable opposition was offered to his scheme, especially by his brother practitioners. A few years later Dr. Engleue made a second attempt, which resulted in the foundation of the Portsmouth, Portsea, and Gosport Hospital. In 1845 a meeting of townsmen decided to build a permanent institution, and there and then subscribed £700 towards the cost.

### *The Royal Portsmouth, Portsea, and Gosport Hospital.*

The earliest record of the Royal Hospital, as it is now more frequently called, is found in a deed dated May 5th, 1847. The Board of Ordinance granted a site in what is now known as Fitzherbert Street at a peppercorn rent for 999 years. The foundation stone was laid by H.R.H. Prince Albert on September 27th, 1847. The hospital was opened on January 2nd, 1849. The buildings cost £2,360. At first there were twelve beds, increased in the following year by the addition of three wards containing twenty beds. In 1868 the building in commemoration of the late Sir Francis T. Baring (first Lord Northbrook), for thirty-nine years member of

*The Borough Mental Hospital.*  
This hospital was opened in 1879. It is situated in beautiful grounds at Milton. There are several three-storied blocks in Gothic style, built in red brick, with Bath stone dressings, connected by corridors on the ground floor. A few years ago

four detached villas were erected in the grounds for the accommodation of private patients. There is a handsome hall for entertainments and a detached chapel in the grounds. There are very complete farm buildings and most of the work is done by patients. The grounds contain 117 acres. Accommodation is available for 922 patients. Dr. Henry Devine is the medical superintendent.

During the last year of the war these buildings were handed over to a medical unit of the United States Army for use as a base hospital.

#### *The Municipal Infectious Diseases Hospital.*

Situated in Milton, this hospital began in 1882 as a small building to accommodate twenty-four patients. At the present time it consists of eleven pavilions and affords accommodation for 265 patients. The buildings stand on a large area of land, which would allow of the erection of hospital tents if required for an unusual epidemic. The most modern pavilion is the observation ward. This consists of four wings radiating from a central room; each of the wings contains five single-bed wards, and as the sides of these are composed of plate glass it is possible for one nurse to keep the whole under observation from the central room. One pavilion containing thirty-two beds is used for advanced cases of tuberculosis.

#### *The Municipal Tuberculosis Service.*

The *Municipal Tuberculosis Dispensary* is a temporary structure situated in Victoria Park, in the centre of the borough. It was first opened in 1911 in a small building, which was soon found to be too small. The present building was opened in 1913, and contains clinical rooms, waiting and dressing rooms, and a laboratory.

*Langstone Hospital* is a small hospital for the treatment of early cases of tuberculosis. It is situated at the south-east extremity of the borough and overlooks Langstone Harbour, near the old locks. At one time a canal ran from here to where the town railway station now stands. A private house was acquired here in 1900 for the treatment of small-pox. In 1911 it was appropriated for the treatment of patients attending the Tuberculosis Dispensary. An iron building has been added, and there is now accommodation for nineteen patients.

In these grounds is another building known as *Beach Lodge*, with nine beds. It is used with great success in the treatment of tuberculous children.

#### *Maternity and Child Welfare.*

The *Municipal Maternity Hospital* is in Elm Grove, Southsea. It was opened in April, 1920, and is intended for the use of necessitous persons only, who are bona fide inhabitants of the borough. There are fourteen beds, and it is recognized as a qualifying training centre for midwives. There were 167 cases admitted in 1920.

*Child Welfare Centres.*—The main centre is in Fratton Road, with subsidiary centres in Portsea, Stanisham, and Eastney. There were more than 22,000 attendances during the last year.

*Natal Maternity Hospital.*—A small maternity home for the wives of sailors in the Royal Navy is situated in Clarence Parade. It is supported by the men of the navy.

#### *The Alexandra Military Hospital.*

Until recently the hospital for the treatment of the sick in the garrison was situated in Lion Terrace, Portsea, in a building at least one hundred years old. The site was sold some years ago to the Admiralty for £80,000. The War Office moved its hospital to a fine site on the southern slope of Portsdown Hill. A fine modern hospital was built here and opened in 1907. The structure is of red brick. The main building consists of an administrative block in the centre, with four blocks for wards attached and a special ward for officers. Each ward contains twenty-two beds and the hospital has accommodation for two hundred patients. In the extensive grounds are several detached wards for observation and for infectious cases. The commanding officers' quarters are on the west of the main block with the officers' mess in the rear.

Still farther back are the company barracks, offices, stores, and recreation room. On the east side are married quarters.

The *Military Medical Reception Station* is situated in Cambridge Road, Southsea. From here those soldiers who are sick and cannot be treated in quarters are removed to the Alexandra Hospital, Cosham.

*Hilsea Hospital.*—This is a small hospital a little way within the fortified lines guarding the entrance to the borough from the mainland. It is used for the treatment of specific cases.

The *Military Families Hospital.*—This hospital was in Lion Terrace, Portsea. It has just been removed to a site at Hilsea. It is for the treatment of the wives and children of the soldiers in the Portsmouth Garrison.

#### *Haslar Hospital.*

In the good old days little provision was made for the care of sick and wounded sailors. After the battle of La Hogue in 1692 many wounded were brought to Portsmouth, and fifty surgeons sent down from London to look after them. Queen Mary made arrangements for some to be treated in the London hospitals of St. Bartholomew and St. Thomas—the only ones of their kind at the time. Orders were also given for the Palace at Greenwich, commenced by Charles II, to be completed and used as a retreat for disabled seamen.

In 1713 we hear of a "Fortune Hospital" near Gosport, where sick and wounded were treated under contract between Nathaniel Jackson and the Lords Commissioners of the

Admiralty. Similar contracts were in existence in the various ports up to the middle of the eighteenth century. Owing to difficulties frequently arising from these contracts it was decided, on the earnest recommendation of the Earl of Sandwich, to found a Royal Hospital at Gosport. The site chosen was known as Hazelar, or Haslar, or Hasleworth. At this spot, on a map of 1603, a castle is marked "Haselworth," but the place is called "Haslehorde" in

THE ROYAL NATIONAL HOSPITAL FOR CONSUMPTION, VENTNOR.

the "Usages of Portsmouth" as far back as the fourteenth century.

Horace Walpole says the architect was Theodore Jacobson. It is of the "Palace" type after the model of a portion of Greenwich Palace designed by Inigo Jones. Local tradition saith that the bricks were made on the spot—hence Clay Hall in the immediate vicinity—and that there are as many bricks in the foundations as there are above ground. The building was commenced in 1746, the front block completed in 1754; the wings were added in 1762 and the chapel on the west side was opened in 1763. It is said to have cost £90,000. The quadrangle of the hospital measures about 7 acres; the area enclosed within the boundary walls is 58 acres.

The hospital was originally intended for 1,800 beds, allowing an air space of 600 cubic feet a head; during the Crimean war it was made to hold 2,000, but the numbers have since been limited to 1,200. Patients on being landed at the pontoon in Haslar Creek are brought up to the hospital by a tramway running right up to the main entrance. The pavilion opposite the main entrances reminds us of the old press-gang days. Here was posted in those days a strong guard to prevent desertion.

Within the hospital there is an interesting museum of pathology and natural history. Amongst the osteological collection are some delicate skeletons set up by a curator who had but two fingers on one hand and none on the other. There are also some rare bird skins.

The hospital is well equipped and the medical school well up to date. All medical officers entering the Royal Navy have to pass through its portals.

By RICHARD J. CYRIAN, M.D., BRUX, M.R.C.S., L.R.C.P.

\* A paper read before the Nantaton and Tamworth Branch of the British Medical Association.

printed forms for distribution by practitioners, with the proviso that the latter should give such additional directions as particular cases may require. The Council advises also that patients should be requested to sign acknowledgements that they have received the information which the law requires practitioners to give them, and has issued a printed form of acknowledgement for the purpose. The practitioner need not, however, inform the patient of the nature of the disease if, in the first place, either the patient's state of health or other circumstances so demand; or, secondly, if the patient is a child under 15 years of age, in which case the necessary information must be imparted to the parents or guardians.

The practitioner must ascertain the source of infection as stated by the patient, provided that the case has not been under the care of another practitioner. Patients who make false statements regarding the source of infection are liable to heavy penalties.

Every case of venereal disease in a communicable stage is compulsorily notifiable by the practitioner to the medical officer of health of the district in which the practitioner resides. It rests with the medical officer of health to forward the notification to the medical officer of health of the district in which the patient resides, provided that the patient and practitioner reside in different sanitary districts.

The following particulars are required to be given on the primary notification forms, printed copies of which are provided.

(i) The kind of disease—that is, acquired syphilis (primary or secondary), congenital syphilis, gonorrhoea, or soft chancre; (ii) the sex, (iii) date of birth, and (iv) address of the patient; (v) particulars of the locality and actual place in which the disease was acquired; (vi) the name, occupation, and address of the person from whom it was acquired; (vii) a space is provided for "remarks."

Notification must be made at latest on the day following that on which the patient was seen.

Reinfection with the same disease for which a patient has already been notified must be treated as a new case and be renotified, but a relapse is not to be regarded as constituting a new case, and need not be renotified. A separate notification form must be sent for each disease—that is to say, if a patient acquires more than one kind of venereal disease simultaneously, each kind must be notified separately and attention drawn to this under the heading of "remarks."

In cases of congenital syphilis the mother's address must be given as that of the place in which the disease was acquired. If the practitioner does not himself treat a case which he is notifying, but passes it on either to another practitioner or to a venereal disease clinic, this must be noted under "remarks."

Notifications must be transmitted to the medical officer of health in sealed envelopes. Envelopes on which the postage has been prepaid are provided for the purpose.

If the patient fails to carry out the directions given him by the practitioner, or ceases treatment without the latter's consent, and without satisfying the latter that he is being treated by another practitioner, the first practitioner must send written notice to this effect to the medical officer of health. The Medical Council suggests, however, that the practitioner should send the patient a notice warning him to resume treatment before reporting him as a defaulter to the medical officer of health, and has issued a printed form for the purpose. On the back of this form are printed the penal clauses of the Act relating to failure to continue treatment for as long as the practitioner requires.

If the patient fails to resume treatment in spite of this warning notice, the practitioner must notify the fact to the medical officer of health. In this case the patient's name must be given. Printed notification forms are provided for the purpose. In the event of wilful opposition on the part of the patient, the practitioner is required to give particulars of this on the form in the space provided for "remarks."

The matter is now in the hands of the medical officer of health. If he considers that extreme measures are not immediately necessary he gives the patient notice to resume treatment within a specified time and to forward a medical practitioner's certificate that he has actually done so, warning him that the matter will be placed in the hands of the health authority if he fails to comply. If the patient on receipt of this notice resumes treatment and sends a certificate to this effect no further action is apparently taken, but the medical officer of health must inform the practitioner who is now treating the case why a warning notice was sent to the patient. Report forms for this purpose, and printed forms of certificates referring to resumption of treatment, have been issued by the Medical Council.

If the patient fails to resume treatment the medical officer of health can bring the matter before his health authority, who, with or without the assistance of the magistrates and the police, can order the patient to submit to examination, and, if found necessary, to treatment, and can compel his removal to hospital if public interests so demand. The

medical officer of health has power to act on his own responsibility in an emergency, pending the decision of the health authority. The patient has the right of appeal if the latter decides against him.

A course of procedure which is very similar to that described above is followed with regard to the person who is stated by the patient to have been the source of infection. If the medical officer of health has reason to believe that the patient's statement on this point is correct, he notifies the accused person to submit to examination within a specified time and to send a medical certificate that he or she has done so. If venereal disease be found in a communicable stage, the person in question can be compelled to undergo treatment. Steps which are similar to those mentioned already are taken in the event of refusal. The medical officer of health, if the accused person resides outside his district, sends the requisite particulars to the medical officer of health of the district concerned.

Persons who are charged with certain offences (apparently such offences as are against public morals) can also be compelled to submit to examination and, if found necessary, to treatment.

If a patient suffering from venereal disease in a communicable stage proposes to marry without the consent of the King, the practitioner who is treating the case must forthwith send notice to this effect to the medical officer of health. The latter must then immediately communicate with the officiating clergyman of whose congregation the patient is a registered member. If a certificate of publication of banns has been or is about to be issued, the minister must at once notify the authorities who are charged with receiving notice of impediments to marriages.

Finally, either the Act itself or the regulations of the Medical Council stipulate the records which the medical officer must keep with regard to venereal diseases, and the kind of information required in annual Health Reports. The Act imposes secrecy upon all persons concerned in its working, but expressly absolves them if information is required under certain circumstances in the course of legal proceedings. It provides also for the transfer of notifications if, for instance, the patient changes his place of residence, enters or is liberated from gaol, or is discharged from the army.

## Paris.

[FROM OUR CORRESPONDENT.]

If we follow the work that is being done simultaneously on the two sides of the Channel, we see that the same problems are being tackled at the same time, and we are tempted to dream of what an International Academy of Medicine might be and to curse the builder of the tower of Babel!

### Acidosis.

The problem of acidosis, which is the order of the day at the National Institute for Medical Research, has recently been the object of impassioned discussions on Tuesday after Tuesday at the Academy of Medicine. According to MM. Desgrez, Bierry, and Rathery, the acidosis of fasting is identical with diabetic acidosis, but M. Labbé sees a radical difference between them. The two theses have been maintained with equal conviction and equal eloquence. The discussion might have gone on for ever had not M. Linossier, at the meeting on March 6th, been able to reconcile, if not the orators, at least the conflicting theses. The short speech with which he intervened I may fairly describe as a model of conciseness and clearness (qualities on which we pique ourselves, perhaps without sufficient grounds, as eminently French). He showed that both the acidosis of fasting and the acidosis of diabetes were to be traced to the same immediate cause, deficient glycolysis. The cause of this defect, however, is different; during a fast the glycolytic function remains intact, but there is too little sugar; in the diabetic the sugar is abundant, but the glycolytic function is impaired. The most learned assemblies sometimes need to be brought back to first principles, and M. Linossier's paper—short as it was—rendered the most signal service to the "docte compagnie."

### Prophylaxis of Whooping-cough.

At the meeting on March 13th Dr. Robert Debré reported the results of his inquiry into the preventive treatment of whooping-cough. He employed the method quite recently introduced by Nicolle and Conseil for the prevention of measles—the injection of the serum of a whooping-cough

patient in the fourth week of the disease—the period when the serum is rich in sensibilizers. If the injection be given at the beginning of the period of incubation it prevents the development of the disease; if given at the end of that period the severity of the disease is considerably diminished; but when once the disease has definitely begun, injection has no effect whatever. We seem now to be on the road to cut short the two epidemic infections that most frequently occur in crèches, and owing to their serious consequences are much to be dreaded.

#### Syphilimetry.

I have already spoken about the systematic campaign against syphilis carried on by the prophylactic institutes founded by Dr. Arthur Vernes. It may be remembered that it is not so much a question of a new therapeutic method as of a means of measuring the luetic infection, of "syphilimetry." After using the Wassermann reaction for some time Dr. Vernes has arrived at certain conclusions with regard to the physical principles on which it may be held to rest. In his opinion it is a matter in particular of optics. Syphilimetry makes it possible to measure the successive levels of the infection step by step, to record them graphically, to observe the effects of the therapeutic measures employed, and to go on diminishing the infection until it has been completely extinguished. Vernes's researches and methods have been described in a series of communications to the Academy of Sciences, which has bestowed upon him certain *prix d'encouragement*, but never before has his method attained the measure of success it enjoys to-day. A propaganda committee has been formed under the patronage of the President of the Republic and the Minister of Hygiene, with the famous philosopher Bergson as president, and a public appeal has been made for subscriptions to a fund to add to the prophylactic institute a teaching establishment where medical practitioners can make themselves acquainted with all the details it is essential to observe in applying a method which is of importance to everybody and has already given fruitful results. The first public subscription at once reached a seven-figure total (in francs). It only remains for me to add that the prophylactic institute itself is presided over by Dr. Roux, and has as its patrons persons of the highest scientific distinction, including the dean and eight professors of the Faculty of Medicine.

#### Hard Times for Scientific Workers.

Existing economic conditions have a most unhappy recoil upon the intellectual worker. One of our most active societies, the Société de Biologie, finds the length of the programmes of its meetings strangely reduced. Before the war its meetings were too short to gather the harvest of the labours of the young investigators in our laboratories. To-day there are hardly any recruits to scientific research. It practically means starvation. Our young people are compelled to obey the dictum *primum vivere*, and none of their masters can withhold their approval. The scandal of the poverty of the intellectuals has, however, led to some reforms, and the chefs de laboratoire (senior demonstrators) have been given salaries sufficient to assure the symbiosis of soul and body. But this measure has not really been of service to science; it has led to a quite unexpected result. Posts which were never regarded as anything but transitional appointments to be held for a limited time are now occupied by incumbents who are not thinking of giving up their places to newcomers.

The question of the rate of exchange has an effect also on our university libraries; their income has not been increased since 1914, and they find themselves too poor to buy publications in the English language. The Parisian libraries have agreed among themselves to subscribe for one copy only of periodicals published at a prohibitive price; this may compel a scientific worker to run about from library to library, and often perhaps to give up his search. On the other hand, our organization is perhaps to blame, for our foreign friends have never failed us when we have asked help in the name of Science. We have been so imbued with the idea of continued progress in the intellectual order that the mind refuses to admit the possibility of regression. And yet, if tools are wanting? If workers are not recruited?

#### Pasteur Centenary.

The celebration of the centenary of Louis Pasteur at the Royal Society of Medicine in London has had a warm and

sympathetic echo here. The *Presse Médicale*, in reporting this function, ends with a remark the symbolism of which is striking. A badge formed by the united flags of the two countries was distributed to the guests, and our contemporary remarks: "The colours may indeed differ, but they remain attached to one and the same staff."

## India.

#### ROYAL COMMISSION ON THE SERVICES.

It was announced some time ago that a Royal Commission on the Services in India was about to be appointed. The terms of reference have now been published, as follows:

Having regard to the necessity for maintaining a standard of administration in conformity with the responsibilities of the Crown for the Government of India and to the declared policy of Parliament in respect of the increasing association of Indians in every branch of the Administration, and in view of the experience now gained of the operation of the system of government established by the Government of India Act in respect of the superior Civil Services in India, to inquire into—

- (1) The organization and general conditions of service, financial and otherwise, of those Services;
- (2) The possibility of transferring immediately or gradually any of their present duties and functions to Services constituted on a provincial basis;
- (3) The recruitment of Europeans and Indians, respectively, for which provision should be made under the constitution established by the said Act and the best methods of ensuring and maintaining such recruitment;

And to make recommendations.

#### THE MILK SUPPLY OF BOMBAY.

The problem of the milk supply of Bombay has been engaging the attention of the corporation for some time, and the municipal commissioner has now made some interesting proposals which if adopted should lead to considerable improvement. Since 1920 endeavours had been made to establish a limited company to take up the production of milk on a large scale; later on reason was found to believe that the Government would be willing to consider certain concessions of land if the corporation were prepared to undertake the production of milk itself. The scheme required an initial capital of 40 lakhs of rupees during the first three years. Long discussions took place between the municipal commissioner and Mr. W. Smith, the Imperial Dairy Export, who agreed that it would be better for private enterprise to be encouraged. A scheme has been put forward to form a company with a capital of Rs.10,00,000, of which it is proposed that the Bombay Corporation should contribute one-fifth, also guaranteeing a yield of 5½ per cent. on the whole capital for the first ten years. The municipality would have the right of inspection and audit, and would appoint one-fifth of the directors.

#### NURSING DEVELOPMENTS IN INDIA.

The Countess of Reading opened the Lady Reading Hostel, the new residence for the nursing staff of the Lady Hardinge Medical College, on January 13th. Major-General MacWatt, Director-General Indian Medical Service, in inviting Lady Reading to open the hostel, thanked her for her deep practical interest in the welfare of the college and its activities in general. Lady Reading pointed out that the institution was the only university medical college for women in India. Of the fourteen students sent up from the college for the last professional examination all had passed, two obtaining honours in pathology and topping the university list of successful candidates, both men and women. The new hostel was another step in the development of the college, and would afford accommodation to the nurses engaged under the Nursing Association, which is yet in its infancy. Much could be done by hospitals, baby clinics, and welfare centres, but it was increasingly clear that the problem of suffering amongst women and children in India could never be fully dealt with until the influences of skilled nursing reached the homes. The association intended to send Indian girls to England to be trained there in the fine traditions of nursing; on their return they would be able to train others in their own country. The total amount contributed to the Hostel and the nursing association amounts to Rs.10,75,000.

## Scotland.

### CLINICAL MEETING OF THE EDINBURGH BRANCH.

THE annual clinical meeting of the Edinburgh Branch of the British Medical Association was held in the Edinburgh Royal Infirmary on February 23rd, and proved a great success. A number of demonstrations, which had been arranged by Mr. F. E. Jardine, were held at different hours throughout the day at the various departments of the Royal Infirmary. Dr. Chalmers Watson, Dr. A. N. Smith, and Mr. J. H. Gibbs gave a laboratory demonstration of the clinical bacteriology of alimentary sepsis, with radiograms of normal teeth, apical suppuration, and changes due to pyorrhoea; Dr. Chalmers Watson also gave a clinical demonstration of alimentary sepsis. Mr. Robson and Dr. Lambie gave a demonstration, in the biochemical laboratory, of the preparation and effect of insulin. A urethroscopic demonstration of venereal diseases was given by Mr. David Lees, who also gave a lantern demonstration of acute venereal conditions. A demonstration on radium and its application in the treatment of disease was given by Dr. Dawson Turner. Dr. John D. Comrie and Dr. Malcolm Smith gave a demonstration of the chemical tests for renal function. Mr. D. M. Greig, conservator of the Royal College of Surgeons, gave a lantern demonstration of pathological specimens, including double tongue and congenital achalasia of the colon. A surgical and medical demonstration was held in the large surgical theatre of the infirmary, which is seated for some 400 persons, and was filled, the audience consisting partly of members of the Branch and other medical practitioners, and partly of final year medical students. Sir Harold Stiles showed a case after removal of extra-dural tumour pressing upon the lumbosacral enlargement, and two other cases. Mr. D. P. D. Wilkie showed two cases after operation for carcinoma of the rectum, using the following methods: (1) Preliminary colostomy, three weeks' interval, during the third week prophylactic inoculations of *B. coli* and streptococcal vaccines, and, the evening before operation, of nucleic acid; (2) twilight sleep, spinal storage, and invert V position. Mr. Pirie Watson showed patients illustrating the use of whole-thickness skin grafting for the alleviation of traumatic deformities of the hand. Dr. W. Stewart gave a demonstration of a simple apparatus for exercising the forearm after fracture. Dr. Murray Lyon showed a case of severe diabetes treated by insulin; and cases were also shown by Professor Edwin Bramwell, Mr. Carlrow, Dr. Fleming, Mr. Hartley, Miss Herzfeld, Dr. McNeil, and others. A pathological museum was arranged in the Pathological Department of the Royal Infirmary and was open all day. A large number of interesting specimens were exhibited, including an album of photographs of paraffin cancer, by Dr. Scott; a series of photographs illustrating plastic nose operations, by Dr. Guthrie; specimens of gall bladders, by Sir Harold Stiles and by Mr. Struthers; specimens of kidneys, by Sir David Wallace; and specimens of early rupture of tubal pregnancy, by Dr. Lamond Lackie. In the evening a dinner took place at the Caledonian Station Hotel, which proved a very enjoyable function. Dr. J. S. Muir, President of the Branch, was in the chair, and Dr. R. A. Bolam, Chairman of Council of the Association, was the guest of the evening, while representatives were also present from some of the other Scottish Branches; the Royal Medical Society was represented by Mr. H. P. Anderson, senior president, and the resident physicians and surgeons of the Royal Infirmary by Dr. Stronach. The honorary secretaries, Dr. John Stevens and Mr. F. E. Jardine, are to be congratulated on the continued success of the annual clinical meeting of the Edinburgh Branch.

### BICENTENARY OF GEORGE WATSON.

An Edinburgh baillie of former days, on being asked to mention the staple products of that city, replied that they were Books, Beer, and Boys. The large and successful schools for boys have long been a feature of the city, and George Watson's College has prepared for entry upon their course of medical study probably a larger number of boys than any other school in the country. Last week this school celebrated the bicentenary of George Watson's death. Watson was born about 1650, and belonged, like George Heriot, his predecessor by a hundred years and founder of another school for boys, to a family of merchants. After a commercial training in Holland, where he also traded to some profit, Watson returned to Edinburgh in 1676 and became cashier

to Sir James Dick, a celebrated Lord Provost of the city. Later, when the Bank of Scotland was originated, he became its accountant, and he did a large business in bills of exchange, chiefly with London correspondents. At his death on April 3rd, 1723, he left several benefactions for the descendants of impoverished Edinburgh merchants, and, among these, £144,000 to establish a hospital, constituted on the Dutch plan, for the education of boys. This school has increased in prosperity and numbers for 200 years. In 1870 the building, which Watson himself had helped to plan, was sold to the managers of the Royal Infirmary and the school moved farther west, but the old building still exists as a central part of the Royal Infirmary.

### OPPOSITION TO EXPERIMENTS ON ANIMALS.

The annual general meeting of the Scottish Society for the Prevention of Vivisection was held last week in Edinburgh. It is an indication of the number of misinformed, though doubtless kindly people who still maintain an attitude antagonistic to the acquisition of further medical knowledge, that the subscriptions and donations for the past year amounted to £515 and the total income to £2,132. Miss Lumsden, in moving the adoption of the report, stated that the number of experiments performed on animals in 1921 had been greater than in the previous year, and the number of experimental licences had also increased, but she admitted that opposition to this form of research received less public encouragement than formerly.

### DENTAL BOARD LECTURES.

A course of four lectures on "The Diseases of the Periodontal Tissues due to Infection in their Relation to Toxaemia," which had been arranged in Edinburgh by the Dental Board of the United Kingdom, concluded last Saturday. The lectures were given in the surgery classroom of the University. The course was intended for and free to dentists and medical practitioners as well as dental students, and was well attended. This first tentative attempt at a post-graduate course organized by the Dental Board has proved so successful that the Board should be encouraged to continue it on a more elaborate scale in future years. The individual lectures, which dealt with the subject from the standpoints of the patho-histology, the local clinical systems, the systemic effects, and the bacteriology, were delivered respectively by Mr. J. Howard Mummery, Mr. J. G. Turner, Sir William Willcox, and Professor E. E. Glynn.

### ROAD WORK FOR SCOTTISH UNEMPLOYED.

A conference of the various local authorities concerned was held last week in Edinburgh to consider the plans for a new arterial road between Glasgow and Edinburgh. The estimated cost is £2,000,000, to be divided equally between the Treasury and the local authorities. It is calculated that the work will provide employment for an average of 4,500 men for two years, and as there are about 100,000 unemployed at present in the two cities, this will be a material alleviation of the situation, since 60 per cent. of the cost will be disbursed in wages. The provision of a thorough road 140 feet wide will greatly facilitate intercourse between the two cities in the future. Various routes have been considered, and that finally approved utilizes portions of the south and middle roads at present existing, in such a way that centres of population like Bathgate, Airdrie, and Bellshill will be avoided, and various new portions and by-passes at villages will be constructed. The route will be the most direct, and will be forty-four miles long.

## Ireland.

### MEDICAL INSPECTION OF IRISH SCHOOL CHILDREN.

SIR JAMES CRAIG, M.D., in the course of his address delivered at a meeting of the Irish National Teachers' Congress held in the Mansion House, Dublin, said that it was better that they should turn their eyes and activities to the future rather than dwell upon the inactivities of the past, for surely they were now at the dawn of a more enlightened era, when they might hope that the health of the people might be regarded as an important function of the State, and when they might endeavour to put in practice the well accepted but rarely adopted maxim that prevention was better than cure. Youth was the time in which the foundation of future physical

well-being should be well and truly laid, and unless they were equipped with a strong and healthy body, all their professional usefulness and scientific attainments would be sadly hampered in the days to come. The broad requirements of a healthy life were few and elementary, but they were essential and should not be regarded as applicable only to the rich. The medical inspection of school children, if properly administered, should prove to be economical in the best sense of the word. Its justification was not to be measured in terms of money, but in the decrease of sickness and incapacity among children and in the ultimate reduction of inefficiency and poverty in after-life arising from physical disabilities. The science of public health included the prevention and extinction of all manner of preventable disease, its distant goal being the rearing of a healthy race and the attainment of a high standard of national physique.

Fundamentally the State control of health inspection depended upon the fact that a large proportion of the children attending the national schools were suffering from preventable and remediable disease. An important fact that they should endeavour to comprehend was that many of the defects were unrecognized either by teachers or parents who alone were in contact with the children. He was quite prepared in that connexion to meet with the criticism that the provision of healthy homes and a plentiful supply of nourishing food would in themselves go far to wipe out much of the ill health and poor physique which were prevalent amongst school children of the day. While people were compelled to live in insanitary tenements or crowded together in damp and airless hovels so long must infectious diseases flourish and a poor standard of general physique be expected. Healthy homes and proper feeding would not by themselves alone cover all the ground that medical inspection claimed to cover. As soon as they had full-time county medical officers of health in the Irish Free State the medical inspection of schools would form part of their duties, and the success of this important work would depend to a great extent on the special qualifications of these health officers. All of them must be possessed with a special diploma in public health, but, in addition to this, it would be most advisable that they or their assistants should have some experience not only in the medical inspection of schools, but also that they should have spent some time in the study of disease as met with in childhood. Efficiency should be the essential qualification in these officers, and if any other consideration prevailed in gaining them their appointments they could not look forward to progress and success. In some instances the county medical officers of health would require assistance in the performance of their duties. Sir James Craig was inclined to think and hope that many qualified medical women would be given opportunities to show that the work entrusted to them in this respect would be performed even more satisfactorily than by medical men.

Under the provisions of the Public Health Bill, which the Minister of Local Government had promised to lay before the Dail within the next few months, there would be health boards appointed by the county councils, and on these health boards he trusted the managers and teachers of primary schools would have due representation, for these health boards would control all medical and public health services of the counties. It would be a duty of the whole-time county medical officers of health who would be appointed under the new Act to advise the County Health Boards in the drawing up of a scheme for the medical inspection and treatment of school children in their respective areas. When such a scheme had received the approval of the Minister for Local Government it would be immediately put into force, and he was not sure that the Minister of Education would have any effective control further than giving his assent to the schemes, and to see that their provisions were complied with. In England, since the passage of the Ministry of Health Act in 1919, the control of the medical inspection of schools rested with the Ministry of Health, while the Board of Education was merely responsible for approving the schemes, paying grants, and carrying on the service. He had said that the schemes would be worked in connexion with the Public Health Service of this country, and he was altogether in favour of a separate Ministry of Health to formulate and control the functions associated with the public health of Saorstát Éireann. This, however, was a departure which the present Government did not view with favour, although it could not be denied that the Irish people were far behind any other civilized nation in their attitude to and their requirements of public health matters.

Having suggested what should be the functions of the medical officer and school nurse, Sir James Craig outlined a programme which they might fairly expect to be put in practice in the inspection and treatment of school children, as follows:

1. A whole-time medical officer of health will be appointed for a county or for several of the smaller counties combined. Part of his regular duties will be to inspect the pupils of the schools in his counties several times a year, and on other occasions as well, in order to ensure that treatment had been carried out in the cases considered by him to require it.
2. A district nurse should be appointed in every dispensary district, whether by the local authority or by voluntary associations. Part of her fixed duties will be to aid in the inspection of pupils, to help to fill their health cards, and to carry out such treatment as she is competent to perform.
3. The treatment of all minor affections should be undertaken by the school nurse and by a whole-time lady assistant to the medical officer of health.
4. The cases requiring institutional treatment will be sent to the district hospital or to the county hospital, but where the treatment by a specialist is necessary then the cases must be sent to the metropolitan special or general hospitals, or to those of the larger towns to which specialists are attached.
5. The provision of dental treatment presents no serious difficulties in the cities or towns where dentists are in practice, but in cases of rural schools a motor car equipped with the necessary apparatus must be provided for the use of the visiting dentist.

Dr. M. Russell, medical officer of health for Dublin, said he was strongly of opinion that a scheme should be evolved by which children should be subjected to medical examination before they entered school. It was reckoned about 35 per cent. of school children under 5 years of age brought into schools physical defects and seeds of diseases which handicapped them in their school life. He would like to see co-operation between the various public health schemes and between the State and local authorities so that they would have medical supervision of the children from their birth till they left school.

#### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

On April 3rd a deputation representing the Royal College of Physicians of Ireland presented an address of welcome to the Governor-General of the Irish Free State, Mr. T. M. Healy, at his official residence in the Phoenix Park.

The members of the deputation were Dr. M. F. Cox, President; Sir William J. Thompson, M.D., Vice-President; Dr. J. Dargan and Dr. R. E. Tottenham, Censors; Sir John W. Moore, M.D.; Dr. T. P. C. Kirkpatrick, Registrar.

#### The Address.

May it please your Excellency.—We, the President and the Fellows of the Royal College of Physicians of Ireland, desire to offer to you our heartiest good wishes on your appointment as Governor-General of the Free State of Ireland. During the two hundred and sixty-nine years of its existence our College has seen many changes in the country, but throughout this long period its policy has ever been to promote the study of medicine and to foster all true efforts for the improvement of the health of the people. Our trust is that in the future we shall be permitted to continue in the pursuit of these aims, and we place freely at the disposal of the Government our services and advice in the remoulding of both medical education and public health administration, which must of necessity follow on the constitution of a new State. To His Gracious Majesty, whom you represent, to the Government of which you are the head, and to yourself, we offer our loyal and dutiful service.—President, Michael F. Cox; Registrar, T. Percy C. Kirkpatrick.

#### The Governor-General's Reply.

I have to thank the President and Fellows of the Royal College of Physicians of Ireland for their good wishes on my appointment. Your College, in an existence of nearly three centuries, has had, I am aware, one beneficent and constantly in view—the fostering of scientific effort for the improvement of public health. You can, I am sure, always rely on the co-operation of the Irish Free State Government in your efforts for the advancement of medical education and sanitary reform. On behalf of His Majesty and of the Government, I express my gratitude for your assurance of the same loyal and dutiful service which has distinguished your College in the past.

The deputation afterwards remained to luncheon with his Excellency.

#### A FREE STATE MINISTRY OF HEALTH.

At a largely attended meeting of Limerick citizens and county representatives held recently in the town hall, it was proposed by Lord Monteagle, seconded by Dr. W. J. O'Sullivan, and passed unanimously:

That this meeting of the Borough and County of Limerick urge on the Irish Free State Government that it should without further delay establish a Ministry of Health for the twenty-two counties on the basis of the recommendations of the report of the Irish Public Health Council.

Dr. T. Hennessy, Irish Medical Secretary of the British Medical Association, attended the meeting by invitation, and delivered an address on the urgent necessity for the reform of Irish Public Health.

#### DISTRIBUTIVE WORKERS' ANNUAL REPORT.

The annual report of the Irish Union of Distributive Workers and Clerks refers to the past year as "the most difficult one yet," and one which taxed the capacity and endurance of the wage-earning classes in this country more than any previous year within living memory. The total income of the organization for the year was £14,443 12s. 6d., an increase of £2,782 11s. 1d. over the previous year. The total expenditure, including £6,598 10s. 8d. in respect of sickness, unemployment, and death benefit and disputes pay, was £11,999 15s. 9d. To the amount set out above in respect of benefit must be added the sum of £4,087 5s. 3d. paid in benefit under the National Health Insurance Act, which brings the total amount paid in benefit for the year up to £10,685 15s. 11d. The excess of income over expenditure was £2,443 16s. 9d. The report of the insurance section of the union expresses the hope that the new legislation contemplated by Dail Eireann in reference to national health insurance will tend to improve the structure of the existing Acts and modify certain regulations contingent on them.

## England and Wales.

#### THE WORK OF VENEREAL CLINICS IN LONDON.

ACCORDING to a report presented to the London County Council at its last meeting, the number of new cases of venereal disease treated at the London clinics in 1922 was 17,762, a decrease of 1,606 on 1921, and of more than 5,000 on 1919 and 1920. Of the new cases, 8,188 were of syphilis, 471 of soft chancre, and 10,632 of gonorrhoea. Of the cases examined during the year 6,049 cases proved to be non-venereal. The ratio of such cases to cases found to be venereal has increased, owing, it is believed, to a growing appreciation by the public of the serious nature of venereal diseases and the necessity for treatment. The most striking feature of the statistical returns is the increase of attendances, both absolutely and in comparison with the number of new cases. The attendances last year numbered 527,635, an increase of 30,000 upon the year before, and of nearly 60,000 upon 1920. This is regarded as evidence of an increasing disposition to continue the treatment necessary, instead of discontinuing attendance as soon as the outward signs of the disease had disappeared. The number of pathological examinations undertaken for the treatment centres was 75,351, and for private practitioners 18,507. The venereal department of St. Thomas's Hospital, which has been expanded and improved, registered 149,682 attendances. If it were possible to have five similar centres in convenient situations, all the cases coming for diagnosis and treatment in the county could be dealt with, but the Public Health Committee of the Council regards it as a wiser policy to spread the work over a larger number of centres. For the ensuing year the scheme, which embraces clinics at eighteen general and ten special hospitals, is to be renewed. The amount voted for the work of the centres is £97,960; in addition, £4,100 is voted for the eight hostels for the reception of pregnant women and children suffering from the disease, £5,000 for a possible additional grant in respect of the new clinic not yet opened at Guy's, and a further £5,000 to cover possible expenditure arising out of the Trevelthinn report. The amount voted for drugs is £3,000, a reduction of £2,000 on the amount hitherto included for this purpose; £2,500 may be spent on propaganda and publicity work. The Council now carries out its publicity work through its own official channels, and the arrangement with the National Council for Combating Venereal Diseases to undertake such work on its behalf has been terminated. Certain neighbouring county and county borough councils which share in the facilities afforded by the London hospitals reduce the expenditure of London proper to about 84 per cent. of the total sum, and three-fourths of the expenditure is recoverable by Government grant.

#### BIRMINGHAM GENERAL HOSPITAL.

The 143rd annual report of the General Hospital, Birmingham, records that the financial position of the institution still gives rise to anxiety, and further effort is called for to

increase income. On the advice of Sir Napier Burnett the Board has appointed a financial secretary who will be responsible, under the house governor, for raising the funds needed to run the hospital, and for the new system of cost accounting. Under this system it will be possible to present a balance sheet showing the exact financial position of the institution. A section of the report, on the need for development of the hospital, states that owing to the great advance in medical and surgical knowledge and practice since the present building was erected twenty-five years ago, and owing also to the increase in the population of the district served, the accommodation and equipment, more particularly in the special departments and staff quarters, have become inadequate. The Medical Committee represented to the Board this inadequacy, both for the treatment of patients and the training of students; the Nursing Committee reported to the same effect; and a special committee has been set up to consider the two reports. In drawing the attention of the governors and subscribers to this situation the Board sets out certain comparisons between 1897 and 1922. In the former year 183 abdominal operations were performed; in the latter, 1,018, and the cases were, in general, of a more serious type, making a very much greater demand upon the surgical and nursing staffs, upon dressings and instruments, and upon every other requirement. Operations on the ear and throat increased from 66 a year to 247 in the same period. There was, of course, no x-ray department in 1897; last year 5,658 photographs were taken, and the department had become inadequate in space and equipment. A very much larger volume of work is being carried out in the pathological department. There is now a radium department, and (as recorded recently in this column) an extern midwifery department has been established. Generally speaking, the Birmingham General Hospital is endeavouring to do an amount of work which it was neither designed nor equipped to deal with, and the time has come to decide whether it is to retain its position as one of the leading hospitals of the country.

#### VENTILATION OF LONDON THEATRES.

New regulations have been issued by the London County Council for ventilating theatres, kinemas, and places of public resort for entertainment or dancing. They are to apply to premises for which new licences are sought and to premises which may be reconstructed, and are to guide the Council in its requirements with regard to existing places when it considers that an improvement in their ventilation is necessary. Before the erection or alteration of the premises is started the approval of the Council must be obtained to the proposed ventilating and heating arrangements, which must be capable of giving a supply of outdoor air at the rate of 1,000 cubic feet per person per hour. It is considered, however, that satisfactory results cannot be obtained in large premises unless the plant is capable of giving a supply of warmed air delivered by fans. It must be capable of maintaining a minimum temperature of 55° F. with full air supply in the building when the outdoor temperature is 30° F., that it does not contaminate the air, that it is not in conflict with the regulations for protection against fire, and that no surface used for warming the air is of a higher temperature than 250° F. The condition of the air is not to be regarded as satisfactory if the amount of carbon dioxide in occupied portions of the premises, taken at a level of 3 ft. 6 in. above the floor, exceeds ten parts in 10,000. Independent means of extraction from lavatories and sanitary conveniences must be provided, so arranged that the air movement does not carry from these places into the public parts.

#### HUMANE SLAUGHTERING.

The London County Council has decided to amend the by-laws regulating private slaughterhouses by the incorporation of the clause from the optional by-laws issued by the Local Government Board in 1915, which provides that "a person shall not in a slaughterhouse proceed to slaughter any animal until the same shall have been effectively stunned, and such stunning shall, except as hereinafter provided, be effected with a mechanically operated instrument suitable and sufficient for the purpose." The exception relates to the Jewish method of slaughter. Hitherto the by-laws of the Council have not contained a provision expressly requiring the stunning of animals. In Switzerland the slaughtering of animals without previous stunning is prohibited by Federal law, and in some cantons mechanically operated instruments
